# Numerical Appraisal of Multhopp's Low-Frequency Subsonic Lifting-Surface Theory 

By H. C. Garner<br>Aerodynamics Division N.P.L.<br>Reports and Memoranda No. 3634*<br>October, 1968

## Summary.

A brief review of oscillatory theories reveals that some of these suffer from a defect that has been corrected in the Algol programme now subject to critical examination. Its features in steady and lowfrequency subsonic flow are outlined, and extensive tabulated results are presented for seventeen planforms. The accuracy and convergence of solutions are studied in relation to arbitrary parameters representing chordwise and spanwise collocation positions, spanwise integration points and the essential central rounding of sweptback wings. Rectangular and other wings with streamwise symmetry, untapered and tapered sweptback wings, slender and curved-tipped wings show progressively slower convergence, and they are examined in respect of overall forces, spanwise loading, local aerodynamic centres, central chordwise loading and oscillatory pitching derivatives. Some new general criteria are recommended for selecting the arbitrary parameters.

Serious inaccuracy arising from the original defect is established, and hence the need to examine theories for general frequency. The residual errors in the Algol programme may stem from high or low aspect ratio demanding extra spanwise or chordwise terms, but the most elusive cause of collocation error in the standard solutions is found to be insufficient central rounding of highly sweptback wings. It is demonstrated, however, that the rounding itself often influences the aerodynamics as much as the standard collocation error and in the opposite sense, so that one correction is useless without the other. Approximate results with both effects taken into account provide a few examples of improved comparisons with exact theory and experiment.

## 1. Introduction.

Consider a planform $S$ in oscillatory vertical motion relative to a free stream of density $\rho$, subsonic Mach number $M$ and of velocity $U$ parallel to the positive $x$-axis. Let the real part of $\bar{z}(x, y) \exp (i \omega t)$ denote the upward displacement of the surface at time $t$, and let the load distribution per unit area over the planform be written as the real part of

$$
\begin{equation*}
\frac{1}{2} \rho U^{2} l(x, y) \exp (i \omega t) \tag{1}
\end{equation*}
$$

Then under the usual linearizing assumptions a double integral equation

$$
\begin{equation*}
\iint_{S} \bar{l}\left(x^{\prime}, y^{\prime}\right) K\left(x^{\prime}-x, y^{\prime}-y, \omega, M\right) d x^{\prime} d y^{\prime}=-\frac{\partial \bar{z}}{\partial x}-\frac{i \omega \bar{z}}{U}, \tag{2}
\end{equation*}
$$

with a complicated kernel function $K$, relates the complex loading function $l$ to the instantaneous flow direction at $(x, y)$ on the planform. Oscillatory lifting-surface theory poses the problem of evaluating $\bar{l}$, when $\bar{z}$ is given. With very few exceptions (see Section 3) mathematical solutions are unobtainable and recourse to numerical analysis is essential.

Garrick ${ }^{1}$ has described the historical background to the subject from the earliest theoretical methods to those available some twelve years ago. He remarks that the problem of three-dimensional flow about wings must be considered to be in a state of continuing development, and the statement remains true. Williams ${ }^{2}$ has contributed a later account of theoretical progress with emphasis on the mathematical formulation. Theoretical methods differ according to whether exponential factors are inserted in the expression (1) or whether the velocity potential over the wing and wake is used in place of 7 in equation (2). The corresponding changes in the kernel function transform the analysis, but of perhaps greater importance are the basic distinctions in the technique of evaluating equation (2) as exemplified in the different classes of solution, viz., strip theory, vortex lattice, box grid, low aspect ratio, high aspect ratio and exact kernel.

The most simple procedure with its powerful empirical capability is strip theory. Van de Vooren and Eckhaus ${ }^{3}$ have developed this for tapered swept wings, and their method has been extended by Eckhaus ${ }^{4}$ to compressible subsonic flow. Such methods are known to give inaccurate aerodynamic damping forces at low frequencies, and their main application is to cases of high aspect ratio and frequency. Vortex lattice and box grid methods for unsteady flow have been developed since the publication of Ref. 1. These exploit changes in mathematical model involving discrete elements of vorticity to simplify the evaluation of equation (2) or some corresponding double integral. Lehrian's ${ }^{5}$ vortex lattice method for incompressible flow and its further development for subsonic and sonic flow by Runyan and Woolston ${ }^{6}$ have been widely used. The chief disadvantage of such methods is the uncertainty resulting from the extra parameters that define the lattice, and there is the burden of proof that the results converge as the lattice spacing is reduced. Although a box method, such as that due to Stark ${ }^{7}$, is probably more promising from the standpoint of establishing accuracy, the same disadvantages have to be overcome. The whole problem of accuracy stems from the fact that there are no exact mathematical solutions for practical planforms, and the change of mathematical model requires justification by numerical analysis alone.

Other methods involve simplifications to the kernel function. One extreme is slender wing theory, formulated for incompressible flow by Garrick ${ }^{8}$ and for compressible flow by Mazelsky ${ }^{9}$. Lawrence and Gerber ${ }^{10}$ have treated wings of low aspect ratio in incompressible flow by splitting the downwash integral into a slender wing term and a residual part in which an approximation is made. The counterparts for wings of high aspect ratio are Cicala's ${ }^{11}$ lifting line theory and the extension for subsonic compressible flow by Reissner ${ }^{12}$ who splits the downwash integral into a two-dimensional term and a residual part with a suitable approximation. Theories such as Refs. 10 and 12 lead to interesting mathematics, but suffer from restricted applicability. Moreover, they stem from the decade before the intensive development of computers and the readjustment of theoretical methods that has ensued.

The use of the exact kernel function is no longer inhibited by computational demands. The basic methods of Watkins et al ${ }^{13}$ and Richardson ${ }^{14}$ differ in that Ref. 13 makes no concessions to expediency of computation, while Ref. 14 implies greater numerical approximation in the pursuit of economy. The latter has been developed by Hsu ${ }^{15}$, and both Lashka ${ }^{16}$ and Davies ${ }^{17}$ have fully mechanized applications of equation (2) with $K$ as formulated in equation (22) of Ref. 13. The procedure is first to evaluate the chordwise integral with respect to $x^{\prime}$, and then to integrate across the span. This latter spanwise integration turns out to be crucial and represents a considerable threat to accuracy.

All the theoretical methods mentioned above (Refs. 3 to 17) apply to general frequencies of oscillation. The mathematical formulation is of course much simpler when only first order effects of frequency are sought. The low-frequency method of Ref. 18 has been developed with a view to the reduction of numerical errors from spanwise integration. In the present report extensive calculations for a wide range of planforms are analysed in order to demonstrate the errors and how they are reduced. The uncertainties that remain are probably no greater than those due to the initial linearization. The convergence of solutions for the aerodynamic loading has been studied with more success for some planforms than others, but the less amenable ones are of more practical interest. Although the primary purpose of the investigation is the appraisal of Ref. 18 as a numerical technique, perhaps of greater importance is the implication that the methods of Refs. 13 to 17 for general frequency are capable of significant improvement by straightforward modification.

## 2. Steady-Flow and Low-Frequency Theories.

Before the essential features of Ref. 18 are described, a brief account of the historical development of Multhopp's low-frequency subsonic lifting-surface theory is desirable. The original steady-flow theory of Ref. 19 was extended to slow pitching oscillations in Ref. 20. The chordwise integration of equation (2) is carried out first. Although Multhopp recognized the need for care in the subsequent spanwise integration and paid attention to the logarithmic singularity in the integrand, his treatment was promptly improved by Mangler and Spencer ${ }^{21}$; with this refinement Multhopp's theory has been widely used for many years. The same basic technique of spanwise integration is carried over into Refs. 16 and 17. Multhopp's original theory was wisely restricted to $N=2$ chordwise terms in the load distribution, and subsequent extensions to larger $N$ have been made without due care. These applications entail collocation points at chordwise positions

$$
\begin{equation*}
\xi=\frac{x-x_{l}}{c}=\frac{1}{2}\left(1-\cos \frac{2 \pi p}{2 N+1}\right) \text { with } p=1,2, \ldots N, \tag{3}
\end{equation*}
$$

which extend closer to the leading edge $x=x_{l}$ as $N$ increases. Let $\bar{m}$ denote an odd number of spanwise integration points between the wing tips, viz.,

$$
\begin{equation*}
\eta=\frac{y}{s}=\sin \frac{\pi \bar{n}}{\bar{m}+1} \quad \text { with } \quad \bar{n}=0, \pm 1, \ldots \pm \frac{1}{2}(\bar{m}-1) . \tag{4}
\end{equation*}
$$

Then it is shown in Ref. 22 that, to ensure 1 per cent accuracy in the calculated steady downwash at the centre of simply loaded rectangular wings of aspect ratio $A$, it is necessary to take $(\bar{m}+1)>4 A$. The analysis of Ref. 22 has been extended to downwash points towards the leading edge of the centreline ( $\eta=0$ ) and reveals inaccuracies greater than 1 per cent if $(\bar{m}+1)<2 A / \xi$. An increase in $N$ with fixed $\bar{m}$ must ultimately lead to divergent results, and it is tentatively recommended in Ref. 18 that

$$
\begin{equation*}
\bar{m}+1 \geqslant 2 A \sec \Lambda_{1} \operatorname{cosec}^{2} \frac{\pi}{2 N+1}, \tag{5}
\end{equation*}
$$

where $\Lambda_{1}$ is the angle of trailing-edge sweepback. Thus for $A=6, \Lambda_{1}=30^{\circ}$ and $N=4$, say, equation (5) would require that $\bar{m}>117$.

Ref. 18 meets this demand by an increase in the number of spanwise integration points to

$$
\begin{equation*}
\bar{m}=q(m+1)-1 \tag{6}
\end{equation*}
$$

where $m$ is the number of collocation sections and $q$ is either unity or an even integer which will need to be increased as $N$ is increased. When $q=1$, the summation of downwash takes the form of equation (22) of Ref. 18 and the calculation is simply that of Ref. 20. As described in Section 2.4 of Ref. 18, the procedure for spanwise integration for $q \geqslant 2$ is to evaluate the downwash at the same collocation sections

$$
\begin{equation*}
\eta_{v}=\cos \theta_{v}=\sin \frac{\pi v}{m+1} \quad \text { with } \quad v=0, \pm 1, \ldots \pm \frac{1}{2}(m-1) \tag{7}
\end{equation*}
$$

in terms of the loading coefficients at the $\bar{m}$ sections of equation (4). Then Multhopp's interpolation polynomial

$$
\begin{equation*}
g(\theta)=(-1)^{\frac{1}{2}(m+1)} \sum_{v=-z}^{z} g\left(\theta_{v}\right) \frac{(-1)^{v-1} \sin \theta_{v} \sin (m+1) \theta}{(m+1)\left(\cos \theta-\cos \theta_{v}\right)} \tag{8}
\end{equation*}
$$

with $z=\frac{1}{2}(m-1)$ is applied to each loading coefficient at every value of

$$
\begin{equation*}
\theta=\frac{\pi}{2}-\frac{\bar{n} \pi}{\bar{m}+1} \tag{9}
\end{equation*}
$$

that occurs from equation (4) in the summation of downwash. Thus the downwash is expressed more accurately as a linear combination of the coefficients in the load distribution

$$
\begin{align*}
I\left(x^{\prime}, y^{\prime}\right)=\exp \left(\frac{i \omega M^{2} x^{\prime}}{\beta^{2} U}\right) \frac{8 s}{\pi c_{n}} & {\left[\gamma_{n} \cot \frac{1}{2} \phi+4 \mu_{n}\left(\cot \frac{1}{2} \phi-2 \sin \phi\right)\right.} \\
& +\kappa_{n}\left(\cot \frac{1}{2} \phi-2 \sin \phi-2 \sin 2 \phi\right) \\
& \left.+\lambda_{n}\left(\cot \frac{1}{2} \phi-2 \sin \phi-2 \sin 2 \phi-2 \sin 3 \phi\right)\right] \tag{10}
\end{align*}
$$

Here the number of functions $\gamma_{n}, \mu_{n}$, etc., is equal to $N, \beta^{2}=1-M^{2}$, the subscript $n$ denotes that

$$
\begin{equation*}
y^{\prime}=y_{n}^{\prime}=s \sin \frac{\pi n}{m+1} \quad \text { with } \quad n=0, \pm 1, \ldots \pm \frac{1}{2}(m-1) \tag{11}
\end{equation*}
$$

and the angular chordwise co-ordinate $\phi$ is given by

$$
\begin{equation*}
x^{\prime}=x_{l n}+\frac{1}{2} c_{n}(1-\cos \phi) \tag{12}
\end{equation*}
$$

The boundary conditions (2) at the $m N$ collocation points, defined by equations (3) and (7), become ordinary linear simultaneous equations to determine the unknowns $\gamma_{n}, \mu_{n}$, etc.

More recent developments in steady subsonic lifting-surface theory are described in Refs. 23 and 24. Zandbergen et al ${ }^{23}$ use a parameter such as $q$ in equation (6), but couple this with a refined technique for spanwise integration. Hewitt and Kellaway ${ }^{24}$ offer a different approach in which the spanwise integration of equation (2) precedes the chordwise integration. Although both these methods have certain advantages
in numerical technique, Ref. 18 is adequate for many purposes and has the additional facility for treating low-frequency oscillations.
The present applications are to wings at a steady uniform incidence $\alpha$ or in oscillatory pitching motion. In steady flow the single solution

$$
\begin{equation*}
\alpha=\alpha_{1}=1 \tag{13}
\end{equation*}
$$

is required, and the load distribution $l=l_{1}$ is obtained in the form of equation (10) without its exponential factor. In most of the oscillatory cases four additional solutions are obtained with

$$
\left.\begin{array}{ll}
\alpha=\alpha_{2}=x / \bar{c} \text { giving } l=l_{2}  \tag{14}\\
\alpha=\alpha_{3} & \text { from equation (23) of Ref. } 18 \text { with } l=l_{1} \\
\alpha=\alpha_{4}=(x / \bar{c})^{2} \text { giving } l=l_{4} \\
\alpha=\alpha_{5} & \text { from equation (23) of Ref. } 18 \text { with } l=l_{2}
\end{array}\right\},
$$

where $\bar{c}$ is the geometric mean chord and a full derivation of $\alpha_{3}$ is given in Ref. 20. To each incidence $\alpha=\alpha_{\mathrm{r}}$ there corresponds a steady wing loading

$$
\begin{align*}
l_{r}=\frac{8 s}{\pi c_{n}} & {\left[\gamma_{n r} \cot \frac{1}{2} \phi+4 \mu_{n r}\left(\cot \frac{1}{2} \phi-2 \sin \phi\right)\right.} \\
& +\kappa_{n r}\left(\cot \frac{1}{2} \phi-2 \sin \phi-2 \sin 2 \phi\right) \\
& \left.+\lambda_{n r}\left(\cot \frac{1}{2} \phi-2 \sin \phi-2 \sin 2 \phi-2 \sin 3 \phi\right)\right] \tag{15}
\end{align*}
$$

from which are calculated the coefficients of lift and pitching moment

$$
\left.\begin{array}{c}
C_{L r}=\frac{1}{\beta} I_{L r}=\frac{\pi A}{m+1} \sum_{n=-z}^{z} \gamma_{n r} \cos \frac{n \pi}{m+1} \quad\left[z=\frac{1}{2}(m-1)\right]  \tag{16}\\
C_{m r}=-\frac{1}{\beta} I_{m r}=\frac{\pi A}{m+1} \sum_{n=-z}^{z} \frac{1}{\bar{c}}\left\{\gamma_{n r}\left(x_{l n}+\frac{1}{4} c_{n}\right)-\mu_{n r} c_{n}\right\} \cos \frac{n \pi}{m+1}
\end{array}\right\}
$$

and also the second moment coefficients

$$
\begin{align*}
-I_{n r}^{*}=\frac{\pi \beta A}{m+1} \sum_{n=-z}^{z} \frac{1}{\bar{c}^{2}} & \left\{\gamma_{n r}\left(x_{l n}^{2}+\frac{1}{2} x_{l n} c_{n}+\frac{1}{8} c_{n}^{2}\right)\right. \\
& \left.-\mu_{n r}\left(2 x_{l n} c_{n}+\frac{3}{4} c_{n}^{2}\right)+\kappa_{n r}\left(\frac{1}{16} c_{n}^{2}\right)\right\} \cos \frac{n \pi}{m+1} . \tag{17}
\end{align*}
$$

These coefficients determine the four pitching derivatives as formulated in equations (39) of Ref. 18 and also those for the reversed planform by equations (38) of Ref. 18.

In the treatment of swept wings major uncertainty arises from the central kink in the planform. Although the form of load distribution (10) or (15) is acceptable for smooth planforms, it is known to lead to logarithmically infinite downwash along a section where a kink occurs. The common practice is therefore to smooth the planform by means of artificial rounding. In order to define the planform at the sections (4), the rounding is formulated according to equation (28) of Ref. 18. When both leading and trailing edges have straight portions in the range

$$
\begin{equation*}
0<y<y_{1}=s \sin \frac{\pi}{m+1} \tag{18}
\end{equation*}
$$

the leading edge and chord in the range $|y| \leqslant y_{1}$ become

$$
\left.\begin{array}{l}
x_{l}(y)=x_{l}\left(y_{1}\right)\left[\frac{|y|}{y_{1}}+\frac{1}{6}\left(1-\frac{|y|}{y_{1}}\right)^{6}\right]  \tag{19}\\
c(y)=c_{r}+\left[\frac{|y|}{y_{1}}+\frac{1}{6}\left(1-\frac{|y|}{y_{1}}\right)^{6}\right] \quad\left\{c\left(y_{1}\right)-c_{r}\right\}
\end{array}\right\}
$$

Here $c_{r}$ is the true central chord and the origin is chosen at the leading apex so that

$$
\begin{equation*}
x_{l}\left(y_{1}\right)=y_{1} \tan \Lambda_{0} \tag{20}
\end{equation*}
$$

where $\Lambda_{0}$ is the angle of leading-edge sweepback. The factor $1 / 6$ in equations (19) is chosen to be consistent with Multhopp's rule in Appendix VI of Ref. 19. Although this standard rounding is controlled by the value of $m$ through equation (18), there is provision for any other desired rounding.

For a given planform, including any artificial rounding and the usual lateral scaling factor $\beta$ in cases of compressible flow, there are only the three integers $m, N$ and $q$ to specify the matrices that govern the simultaneous equations for $\gamma_{n}, \mu_{n}$, etc. The programme of Ref. 18 limits the number of chordwise terms to $N \leqslant 4$ and there are interdependent restrictions on $m, N$ and $q$ imposed by the capacity (32K) of the N.P.L. KDF9 computer and an arbitrary maximum running time of 45 minutes. The tables in Section 1 of Ref. 18 illustrate the restrictions and typical running times. In the present applications it is possible to study the convergence of the theoretical results with respect to each of the parameters. The extent to which full convergence is frustrated by the restrictions is dependent on the planform and the aerodynamic quantity being considered. To be necessary, the method must show inadequate convergence with respect to $N$ when $q=1$. To be successful, it must show convergence with respect to $q, m$ and $N$.

## 3. Numerical Results.

Calculations have been made for the seventeen planforms listed in Table 1. When both leading and trailing edges are straight, the planform is defined by the tabulated values of aspect ratio $A=2 s / \bar{c}$, $c_{r} / \bar{c}, \tan \Lambda_{0}$ and $\tan \Lambda_{1}$, themselves related by

$$
\begin{equation*}
c_{r} / \bar{c}=1+\frac{1}{4} A\left(\tan \Lambda_{0}-\tan \Lambda_{1}\right) . \tag{21}
\end{equation*}
$$

The exceptions are Planforms $4,6,15,16$ and 17 for which additional formulae or data are included. The final column of Table 1 gives references to earlier work on some of the planforms. Stark ${ }^{\prime} \mathrm{s}^{25}$ theory has been applied to the rectangular wing $(A=2)$. The circular planform is one example of an exact solution by Van Spiegel ${ }^{26}$, whose theory and corrected results are presented by Benthem and Wouters ${ }^{27}$. Other examples where exact theory is available are the very slender delta and gothic planforms $(A=0.0001)$ to which Garrick's ${ }^{8}$ theory is applicable. Planforms 10,11 and 17 are chosen because they have formed the
subjects of earlier theoretical and experimental research (Refs. 30,31 and 35 ). Although comparison with experimental results forms a very minor part of the present investigation, five of the remaining planforms have been chosen because measured aerodynamic data were available in Refs. 28, 29, 32, 33 and 34. These represent a wide range of shapes and offer the opportunity to examine the difficulties associated with high and low aspect ratio, leading-edge and trailing-edge sweepback and curved tips.
The tabulated theoretical results for each of the planforms are summarized in Table 2. Tables 3 to 34 concerning steady flow ( $\alpha=1$ ) are sub-divided into complete solutions and total forces (Tables 3 to 22 ) and into spanwise distributions of lift and aerodynamic centre (Tables 23 to 34). The next sequence involves oscillatory pitching motion, the coefficients being given in Tables 35 to 42 and the pitching derivatives in Tables 43 to 48. As the discussion unfolds, it will become clear that one crucial source of inaccuracy is associated with the need for artificial central rounding of sweptback wings, as defined in equations (18) to (20). Some attempts have been made to reduce these errors and to evaluate the effect of rounding, and Tables 48 to 50 are included primarily for this purpose.

### 3.1. Steady Flow.

In the case of 7ero frequency Ref. 18 reduces to steady flow, and altogether over 200 solutions have been obtained for the planforms listed in Table 1 at unit incidence. The non-dimensional loading

$$
\frac{\Delta p}{\frac{1}{2} \rho U^{2}}=\Delta C_{p}=l
$$

at the sections $\eta=\sin \frac{\pi n}{m+1}$ are given by equation (15) where the subscript $r(=1)$ may be omitted. The solutions in Tables 3 to 22 are $N$ sets of functions $\gamma_{n}, \mu_{n} \ldots$, e.g. when $N=4$,

$$
\gamma_{0}, \gamma_{1}, \ldots \gamma_{z} ; \mu_{0}, \mu_{1}, \ldots \mu_{z} ; \kappa_{0}, \kappa_{1}, \ldots \kappa_{z} ; \lambda_{0}, \lambda_{1}, \ldots \lambda_{z}
$$

where $z=\frac{1}{2}(m-1)$. The local lift coefficient and aerodynamic centre are given by

$$
\begin{equation*}
C_{L L}=\frac{4 s \gamma_{n}}{c_{n}} \tag{22}
\end{equation*}
$$

and

$$
\begin{equation*}
X_{a c}=\frac{1}{4}-\frac{\mu_{n}}{\gamma_{n}} . \tag{23}
\end{equation*}
$$

The total lift and moment about the origin at the leading edge of the root chord are evaluated as coefficients $C_{L}=C_{L 1}$ and $C_{m}=C_{m 1}$ from equations (16). The centre of lift or aerodynamic centre acts at a distance $x_{a c}$ downstream of the origin and is readily evaluated as

$$
\begin{equation*}
\frac{x_{a c}}{\bar{c}}=-\frac{C_{m}}{C_{L}} . \tag{24}
\end{equation*}
$$

The spanwise centre of pressure of the half wing is defined as

$$
\begin{equation*}
\bar{\eta}=\int_{0}^{1} \frac{c C_{L L}}{\bar{c} C_{L}} \eta d \eta=\frac{2 A}{C_{L}} \int_{0}^{1} \gamma \eta d \eta, \tag{25}
\end{equation*}
$$

where $c C_{L L} / \bar{c} C_{L}$ represents the spanwise loading and the distribution of $\gamma$ satisfies equation (8). For symmetrical spanwise loading we may write

$$
\begin{equation*}
\gamma=\sum_{k=0}^{z} a_{2 k+1} \sin (2 k+1) \theta \tag{26}
\end{equation*}
$$

Thus $C_{L}=\frac{1}{2} \pi A a_{1}$, and it follows from equations (8), (25) and (26) that

$$
\begin{equation*}
\bar{\eta}=\frac{4}{\pi a_{1}} \sum_{k=0}^{z} \frac{(-1)^{k+1} a_{2 k+1}}{(2 k-1)(2 k+3)}, \tag{27}
\end{equation*}
$$

where

$$
\begin{equation*}
a_{2 k+1}=\frac{2}{m+1} \sum_{\nu=-z}^{z} \gamma_{v} \sin (2 k+1) \theta_{v} . \tag{28}
\end{equation*}
$$

A typical result, for $m=11$, is

$$
\begin{equation*}
\bar{\eta}=\frac{0.02671 \gamma_{0}+0.24372 \gamma_{1}+0.43514 \gamma_{2}+0.49904 \gamma_{3}+0.43349 \gamma_{4}+0.24980 \gamma_{5}}{0.50000 \gamma_{0}+0.96593 \gamma_{1}+0.86603 \gamma_{2}+0.70711 \gamma_{3}+0.50000 \gamma_{4}+0.25882 \gamma_{5}} . \tag{29}
\end{equation*}
$$

Nearly every solution that has been obtained with $\bar{m}=m$ or $q=1$ is seen to be inadequate. There are examples in Tables $3,4,5,7,8,10,12,13,17,18,20,21$ and 22 , and the behaviour of $\kappa_{n}$ or $\lambda_{n}$ with increasing $q$ illustrates the point at once. In some cases $C_{L}$ and $C_{m}$ prove to be unacceptable, and there is no doubt that the method of Ref. 18 (with $q \geqslant 2$ ) is necessary. More careful study is required to establish whether the method converges satisfactorily. Fig. 1 shows the behaviour of local aerodynamic centres from equation (23) for simple rectangular planforms. Convergence with respect to $m$ is so perfect that $X_{a c}$ can be plotted against a logarithmic scale of $(\bar{m}+1$ ) with insignificant changes as $m$ is increased from 7 to 15 . The horizontal lines joining points corresponding to the larger values of $(\bar{m}+1)$ show convergence with respect to $\bar{m}$ or $q$. The separate results for $N=2,3$ and 4 chordwise terms show perfect convergence for the centre section when $A=2$ and satisfactory, but slower, convergence with respect to $N$ near the tip when $A=4$. The results for the smaller aspect ratio when $\bar{m}=m=7$ illustrate, perhaps surprisingly, how the previous method (Ref. 18 with $q=1$ ) diverges with respect to $N$. A less favourable example is the highly swept Planform 16 with curved tips considered in Fig. 2 where, as in Fig. 1, the false zeros and large scale tend to exaggerate the discrepancies. The lift slope $\partial C_{L} / \partial \alpha$ and the overall centres of pressure $\bar{\eta}$ and $x_{a c} / \bar{c}$ are plotted against $(\bar{m}+1)$. The effect of increasing $m$ from 15 to 31 is now discernible, but not large. Convergence with respect to $\bar{m}$ is slower, but satisfactory. Convergence with respect to $N$ would appear to be fairly good for $q=1$ and $q=8$ (respectively $\bar{m}+1=16$ and 128 when $m=15$ ), but this is illusory in the former case and the resulting lift slope is about 7 per cent too high and the aerodynamic centre nearly $0.04 \bar{c}$ too far forward.

These examples serve as preliminary illustrations. The different types of planform, in steady and oscillatory flow, will be considered in Section 4 where each sheds new light on the numerical appraisal. An attempt is made in Section 5 to recommend a suitable choice of $m, N$ and $\bar{m}$. A critical study of the use of artificial central rounding is deferred until Section 6.

### 3.2. Oscillatory Flow.

The output from the Algol programme of Ref. 18 can give the coefficients

$$
\begin{equation*}
I_{L r}(r=1,2, \ldots 5), \quad-I_{m r}(r=1,2, \ldots 5) \quad \text { and } \quad-I_{m r}^{*}(r=1,2) \tag{30}
\end{equation*}
$$

from equations (16) and (17). The coefficients are listed from various solutions for thirteen of the planforms in Tables 35 to 42, but in the last instance and in a few other solutions not all twelve coefficients are available. But there are always sufficient to determine the pitching derivatives defined by
where the frequency parameter $\bar{v}=\omega \bar{c} / U, \theta_{0}$ is the amplitude of pitching oscillation and the pitching moment is nose-up and about the axis $x=x_{0}$. In terms of the coefficients (30)

$$
\left.\left.\left.\begin{array}{rl}
-z_{\theta}= & \frac{1}{2 \beta} I_{L 1} \\
-m_{\theta}= & \frac{1}{2 \beta}
\end{array}\right]-\frac{x_{0}}{\bar{c}} I_{L 1}+\left(-I_{m 1}\right)\right] \quad \begin{array}{rl}
-z_{\dot{\theta}}= & \frac{1}{2 \beta}
\end{array}\left[-\frac{x_{0}}{\bar{c}} I_{L 1}+\frac{\beta^{2}-M^{2}}{\beta^{2}} I_{L 2}+\frac{1}{\beta^{2}} I_{L 3}+\frac{M^{2}}{\beta^{2}}\left(-I_{m 1}\right)\right]\right\} \text { - } \begin{aligned}
=\frac{1}{2 \beta} & {\left[\frac{x_{0}^{2}}{\bar{c}^{2}} I_{L 1}-\frac{x_{0}}{\bar{c}}\left\{\frac{\beta^{2}-M^{2}}{\beta^{2}} I_{L 2}+\frac{1}{\beta^{2}} I_{L 3}+\frac{1}{\beta^{2}}\left(-I_{m 1}\right)\right\}\right.} \\
& \left.+\left\{\frac{\beta^{2}-M^{2}}{\beta^{2}}\left(-I_{m 2}\right)+\frac{1}{\beta^{2}}\left(-I_{m 3}\right)+\frac{M^{2}}{\beta^{2}}\left(-I_{m 1}^{*}\right)\right\}\right] \tag{32}
\end{aligned}
$$

where $\beta^{2}=1-M^{2}$.
Among the various applications of the reverse-flow theorem considered by Lehrian and the present author, Section 5.1 of Ref. 36 gives the formulation for low-frequency pitching oscillations. The derivatives (32) may be expressed in terms of the coefficients (30) for the reversed wing, i.e. the given planform in a stream of reversed direction and unchanged Mach number. These coefficients are denoted by $\bar{I}_{L r},-\bar{I}_{m r}$ and $-\bar{I}_{m r}^{*}$. It can be shown that there are precise relationships between the two sets of coefficients, which are conveniently expressed in matrix form as follows.

$$
\left[\begin{array}{c}
I_{L 1}  \tag{33}\\
I_{L 2} \\
I_{L 4} \\
-I_{m 1} \\
-I_{m 2} \\
-I_{m 4} \\
-I_{m 1}^{*} \\
-I_{m 2}^{*}
\end{array}\right]=\left[\begin{array}{cccccccc}
1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
\lambda & -1 & 0 & 0 & 0 & 0 & 0 & 0 \\
\lambda^{2} & -2 \lambda & 1 & 0 & 0 & 0 & 0 & 0 \\
\lambda & 0 & 0 & -1 & 0 & 0 & 0 & 0 \\
\lambda^{2} & -\lambda & 0 & -\lambda & 1 & 0 & 0 & 0 \\
\lambda^{3} & -2 \lambda^{2} & \lambda & -\lambda^{2} & 2 \lambda & -1 & 0 & 0 \\
\lambda^{2} & 0 & 0 & -2 \lambda & 0 & 0 & 1 & 0 \\
\lambda^{3} & -\lambda^{2} & 0 & -2 \lambda^{2} & 2 \lambda & 0 & \lambda & -1
\end{array}\right]\left[\begin{array}{c}
\bar{I}_{L 1} \\
-I_{m 1} \\
-\bar{I}_{m 1}^{*} \\
\bar{I}_{L 2} \\
-\bar{I}_{m 2} \\
-\bar{I}_{m 2}^{*} \\
\bar{I}_{L 4} \\
-I_{m 4}
\end{array}\right]
$$

and

$$
\left[\begin{array}{r}
I_{L, 3}  \tag{34}\\
I_{L:} \\
-I_{m 3} \\
-I_{m 5}
\end{array}\right]=\left[\begin{array}{rrrr}
1 & 0 & 0 & 0 \\
\lambda & -1 & 0 & 0 \\
\lambda & 0 & -1 & 0 \\
\lambda^{2} & -\lambda & -\lambda & 1
\end{array}\right] \quad\left[\begin{array}{r}
\bar{I}_{L 3} \\
-\bar{I}_{m 3} \\
\bar{I}_{L 5} \\
-\bar{I}_{m 5}
\end{array}\right]
$$

where $\lambda=c_{r} / \bar{c}$ and the length $c_{r}$ enters in as the displacement between the origins of the two co-ordinate systems. Both square matrices have the property of self-inversion, so that the column matrices on the two sides of equation (33) or (34) can be interchanged. The numerical results do not satisfy these equations exactly, and proof of inaccuracy due to inadequate collocation or spanwise integration can often be established.
Woodcock ${ }^{37}$ and Dat et al ${ }^{38}$ have considered the accuracy of collocation solutions to oscillatory problems in subsonic lifting-surface theory. Ref. 37 reveals large discrepancies for the present Planforms 1,4 and 11 at high frequency parameter, and it is important to resolve any similar discrepancies at low frequency. Ref. 38 suggests that lifting-surface theory can be optimized in aeroelastic applications with the aid of the reverse-flow theorem, and it will be relevant to study the convergence of the pitching derivatives from equations (32), not only with the usual coefficients from direct flow but also by reverse flow with the aid of equations (33) and (34).
The peculiar problems of the various types of planform will be discussed in Sections 4.1 to 4.6. But, as for steady flow, two figures have been prepared to illustrate the convergence of pitching derivatives under favourable and adverse circumstances. In Fig. 3 all four pitching derivatives are plotted against a logarithmic scale of $(\bar{m}+1)$ for Planform 6 having a smooth hyperbolic leading edge and constant chord. The small slopes of the lines joining points corresponding to the larger values of $\bar{m}$ show satisfactory convergence, although the damping derivatives are somewhat slower to settle. The results for $\bar{m}=95$ indicate satisfactory convergence with respect to $m$ and $N$. The points (0) for $m=\bar{m}=15$ show relatively poor convergence with respect to $N$ when $q=1$, but the discrepancies for $N=4$ nowhere exceed 0.02 . Planform 12 has high aspect ratio $A=8$ and a central kink typical of sweptback wings, and both these features would be expected to aggravate convergence. Figure 4 shows the direct pitching derivatives for an axis $x_{0}=2 \bar{c}$ against a logarithmic scale of $(m+1)$. With $N=3$ throughout, convergence is sought firstly with $q=1$ and secondly with $\bar{m}=95$ up to the limit of $m$ imposed by the KDF9 computer. The two processes show a tendency to approach a common limit, but for neither $m_{\theta}$ nor $m_{\theta}$ do the respective curves come within 0.03 of each other. The comparable discrepancies in Fig. 3 for the smooth edges and lower aspect ratio are of order 0.002 .

## 4. Convergence of Solutions.

The planforms of Table 1 have been chosen from different standpoints, and it is convenient to group them in the following sub-sections. The rectangular wings (Planforms 1,2,3) cover a range of aspect ratio, and the rate of convergence with respect to $\bar{m}$ shows an inverse correlation with $A$. The wings with streamwise (fore-and-aft) symmetry for which oscillatory calculations have been made (Planforms 2, 4, 5) form a natural group and are used for studying numerical results from direct and reverse flow. The three wings of constant chord with $A=4$ (Planforms 2, 6,7) show the separate effects of sweepback and the central kink. Planforms 8 to 12 constitute an assortment of tapered sweptback wings; the effect of Mach number is considered, and the problems posed by Fig. 4 are elaborated. The slender wings (Planforms 13, 14, 15) include one that is not-so-slender with better convergence properties illustrated by the chordwise loading; the results for the really slender wings $(A=0.0001)$ are subjected to comparison with exact theory. Wings with curved tips (Planforms 16, 17) show the greatest discrepancies when $q=1$ and peculiarly slow convergence associated with the tips.

### 4.1. Rectangular Wings.

Selected solutions for the rectangular wings of aspect ratios 2 and 4 at unit incidence are given in

Tables 3, 4 and 5 . In Table 3 the subscript $n$ of the four loading functions $\gamma_{n}, \mu_{n}, \kappa_{n}$ and $\lambda_{n}$ relates to equations (10) and (11) with $m=15$. It is seen that the outermost values $\kappa_{6}$ and $\lambda_{6}$ converge more rapidly with respect to $q$ than $\kappa_{0}$ and $\lambda_{0}$ do; the more central sections of the wing show discrepancies in the fourth decimal place up to $\bar{m}=127$, while by $\bar{m}=47$ these have practically disappeared near the tip. The last two columns of Table 3 are in remarkable agreement, showing little change as $m$ is increased from 7 to 15 . Furthermore, unpublished solutions for $m, N, q=15,4,2$ and $31,4,1$ are identical to six decimal places. An independent check from Table 3 of Ref. 25 gives in the present notation $C_{L}=2.471$ and $x_{a c}=0.2089 \bar{c}$, which are in very satisfactory agreement with values in the present Table 3.

In Table 4 the major part of the error with $q=1$ is eliminated as $q$ is increased to 2 . It will be found that the spanwise integration in Hsu's ${ }^{15}$ theory is virtually equivalent to that from Ref. 18 with $q=2$ and is commended thereby. Solutions for $A=4, N=4$ and the same value of $\bar{m}$ in Tables 4 and 5 show surprisingly little effect of increasing $m$ from 7 to 15 . The first two and last columns of Table 5 demonstrate excellent convergence with respect to $N$ at the centre section and slower convergence near the tip as in Fig. 1.

Table 23 presents material for a fuller analysis of local aerodynamic centres on the two rectangular wings, and Table 24 gives further results for the high aspect ratio $A=8$. Unless the consequences of Ref. 18 are fully appreciated, a solution for this wing with $m, N, q=23,3,1$ and 36 collocation points on the half wing might seem to promise good accuracy. Yet Table 24 shows that the lift slope $\partial C_{L} / \partial \alpha$ is more than 2 per cent low when $q=1$, while the local $X_{a c}$ at $\eta=0$ is $0-002 c$ too far aft when $q=1$ and nearly $0.004 c$ too far forward when $q=2$. These findings are rationalized in Fig. 5, where the errors in the two quantities are plotted convincingly against $(\bar{m}+1) / \beta A$ from the available data for $N=3$. Similar curves with slower convergence can be drawn for $N=4$. As foreshadowed in Ref. 22, wings of high aspect ratio pose a major problem, especially when larger numbers of chordwise terms are needed.

Results for oscillatory flow in Tables 35 and 43 will be discussed in Section 4.2.

### 4.2. Wings with Streamwise Symmetry.

The oscillating circular planform in incompressible flow is a notable exception to the intractable methematical problems of lifting-surface theory. The analysis is due to Van Spiegel ${ }^{26}$ and a correction to his numerical result for the pitching damping is given by Benthem and Wouters in Table 2 of Ref. 27. We consider first the solutions by the collocation method of Ref. 18 for steady flow in Table 6. Convergence with respect to $q$ is very good, except near the tip as indicated by the values of $\lambda_{5}$ when $m=11$ and $N=4$. The solutions with $N=2$ and 3 show a small effect of reducing $m$ to 5 . The results for the largest values of $q$ are tabulated below and show remarkable convergence with respect to $N$ in perfect agreement with exact theory.

| Solution | $\partial C_{L} / \partial \alpha$ | $x_{a c} / \bar{c}$ |
| :---: | :---: | :---: |
| $N=2$ | 1.7888 | 0.3015 |
| $N=3$ | 1.7906 | 0.3052 |
| $N=4$ | 1.7903 | 0.3049 |
| Exact | 1.7902 | 0.3049 |

The aerodynamic centre is plotted against $q$ at the top of Fig. 6. It must be admitted that the circular planform is a favourable case with smooth edges and low aspect ratio.

Table 25 gives the local aerodynamic centres for circular and symmetrically tapered planforms. The results for the circular planform ( $A=1.27$ ) show excellent convergence with respect to $m, N$ and $q$ except near the tip where in no respect is the convergence quite complete. Unfortunately there are no reliable numerical results from exact theory to form a basis for comparison. The symmetrically tapered wing
( $A=4.33$ ) shows good convergence with respect to $q$ and, except near the centre section, little effect of increasing $m$ from 11 to 23 . Although $(m+1)=2 A$ is acceptable for rectangular wings, $(m+1) \geqslant 4 A$ seems desirable for both the others.

Wings with streamwise symmetry present a convenient opportunity to use the relationships in direct and reverse flow, since the coefficients $\bar{I}_{L r}=I_{L r}$ and $\bar{I}_{m r}=I_{m r}$. Thus by equations (33) the aerodynamic centre may be calculated from reverse flow to be

$$
\begin{equation*}
\frac{x_{a c}}{\bar{c}}=\frac{c_{r}}{\bar{c}}-\frac{I_{L 2}}{I_{L 1}} . \tag{35}
\end{equation*}
$$

This is compared with equation (24) for direct flow against the logarithmic scale of $q$ in Fig. 6. The results with $N=3$ are shown to converge to good accuracy within 0.0005 for the rectangular wing ( $A=4$, $m=15$ ), but for the symmetrically tapered wing the discrepancies between equations (24) and (35) are 0.004 when $m=11$ and 0.002 when $m=23$ and show little sign of disappearing as $q$ is increased. Such uncertainty, though tolerable, is a danger signal.
The coefficients for the three wings in oscillatory flow are given in Table 35 and the derivatives have been calculated for pitching motion about the axes of symmetry from equations (32) with $\beta=1$. Table 43b shows excellent results for the circular wing, good convergence of $z_{\dot{\theta}}$ and $m_{\theta}$ with respect to $N$ close to exact theory and reverse-flow checks that only reveal errors in the fifth decimal place. Damping derivatives for the rectangular and symmetrically tapered wings with $N=3$ from Tables 43a and 43c are plotted against $q$ in Fig. 7 together with the corresponding results when the reverse-flow equations (33) and (34) are used for the coefficients. The upper diagram shows $-z_{\hat{\theta}}$ for the rectangular wing with good correlation when $q=4$ and 6 , but a substantial error of 8 per cent when $q=1$. The lower diagram shows $-m_{\theta}$ for the symmetrically tapered wing with a persisting discrepancy of nearly 0.01 between direct and reverse flow for $m=11$, that is halved when $m=23$ and is compatible with eventual convergence with respect to $m$.

### 4.3. Wings of Constant Chord.

Planforms 2, 6 and 7 all have constant chord and aspect ratio 4 and are considered in incompressible flow. The first two have smooth edges and illustrate the effect of sweepback without the complication of a central kink. The last two have 45 deg of sweepback at the tip and illustrate the effect of the kink.

From the solutions for steady flow in Tables 4,5,7 and 8 there is found to be no appreciable worsening of the convergence with respect to $q$ due to the sweepback or kink. Neither of the swept wings exhibits the same remarkable convergence with respect to $m$ as is noted for the rectangular wing in Section 4.1 : the last two columns of Table 8 show somewhat poorer convergence for the skinked straight-edged planform. Moreover, the larger values of $\lambda_{0}$ suggest that there could be a local problem of convergence with respect to $N$ at the central kink as well as near the tip. The local aerodynamic centres for the three wings are fully listed in Tables 23b, 26a and 26b, and some of the spanwise distributions with $N=4$ are plotted in Fig. 8. For the rectangular wing there is no effect of $m$ and the small effect of $q$ barely exceeds $0-003$. In the case of hyperbolic edges there is a minor effect of $m$ and that of $q$ exceeds 0.01 locally. When there is the central kink, the effect of $q$ is similar near the tip, but near the centre section both $m$ and $q$ produce changes of 0.035 in $X_{a c}$ and its distribution, referred to the planform without artificial rounding, is less well defined.

The coefficients for oscillatory motion are given in Tables 35a, 36 and 37. Convergence with respect to $q$ is evidently less sensitive to sweepback than to aspect ratio (Section 4.1), but the kinked wing introduces a marked deterioration in convergence with respect to $m$. The four pitching derivatives for the swept wings have been calculated from equations (32), and their convergence for the hyperbolic-edged wing has already been demonstrated in Fig. 3. The results for both wings in Table 44 include sets of derivatives calculated from solutions with $m, N, q=15,3,6$ in reverse flow. The pitching damping derivative $-m_{\theta}$ is plotted against axis position $x_{0} / \bar{c}$ in Fig. 9 . The effect of $N$ is indiscernible, and for each wing the full curve represents $N=3$ and $N=4$. But, whereas for the hyperbolic edges the curve from reverse flow is
also indiscernible, the broken curve for the kinked wing reveals discrepancies in $m_{\theta}$ of order 10 per cent and exceeding 0.1 for rearward axes. This is an order of magnitude greater than likely residual errors from insufficient $q$ and $N$ and still several times what would be expected from the poorer convergence with respect to $m$. For conventional sweptback wings this aspect of numerical solutions needs more detailed study.

### 4.4. Tapered Sweptback Wings.

The five planforms in this category were all chosen for comparison with other work beyond the scope of the present report. Planforms 8,9 and 12 relate to steady measurements of pressure distribution, and Planforms 10 and 11 to particular oscillatory applications (Refs. 28 to 32). It will not be necessary to discuss all the tabulated results, and we shall now concentrate mainly on the effects of $m$ and $M$.

The solutions for the cropped delta wing at $M=0.8$ in Table 10 include a set of three with $N=3$, $\bar{m}=31$ and $m=7,15$ and 31. Although the effect of $m$ is quite small, the convergence with respect to $m$ is unconvincing. Tables 11 to 13 give results, all with $m=15$, for an arrowhead wing of identical leadingedge sweepback at $M=0,0.6$ and 0.8 . Table 11, comprising solutions for the two lower Mach numbers with $N=2,3,4$ and $q=2 N$. shows excellent convergence with respect to $N$ and no adverse effect of compressibility. Figure 10 is prepared from the more comprehensive results for $M=0 \cdot 8$. The lift slope and aerodynamic centre are plotted against $N$ for three conditions, $q=1$ showing errors of about 3 per cent, $q=2$ showing great improvement, and $q=2 N$ when the convergence is really convincing. For $N=3, x_{a c} / \bar{c}$ is plotted against $M$ in the lower part of Fig. 10; although the correct trend is predicted with $q=1$, the curve for $q=6$ shows that the error is of the same order as the effect of compressibility. Tables 27 and 28 give the calculated local aerodynamic centres at $M=0.8$ for these wings and Planform 10 of lower aspect ratio and sweepback. The latter with $N=4$, fixed $\bar{m}=95$ and $m=7,11$ and 15 shows no alarming effects on spanwise loading or $X_{a c}$, but it is the use of the parameter $m$ for high aspect ratio and sweepback that needs critical examination.

Planform 12 has aspect ratio $A=8$ and quarter-chord sweepback of 45 deg. As has already been seen in Fig. 4 (Section 3.2), oscillatory pitching derivatives for this wing at $M=0$ converge inconsistently with respect to $m$; no common limit is approached with $q=1$ and $\bar{m}=95$ before the capacity of the KDF9 computer is exceeded. Results for steady flow are contained in Tables 15, 29, 30 and 31. The overall forces from eleven solutions with $N=3$ are plotted against the same logarithmic scale of $(m+1)$ in Fig. 11, where besides the values for $q=1$ and $\bar{m}=95$ there are some further results in which the artificial rounding is defined by equations (18) to (20) with $m=15$, i.e. with $y_{1}=s \sin (\pi / 16)$, while the number of collocation sections $m$ is increased. Under these conditions both the lift slope and aerodynamic centre lie between the best values obtainable with $q=1$ and $\bar{m}=95$ and the uncertainties appear to be reduced to $\pm 1 \frac{1}{2}$ per cent in $\partial C_{L} / \partial \alpha$ and $\pm 0.015$ in $x_{a c} / \bar{c}$. The local load grading $c C_{L L} / \bar{c} C_{L}$ and $X_{a c}$ at $\eta=0$ are plotted similarly in Fig. 12, where by contrast the uncertainties are broadened when the fixed $m=15$ rounding is considered and reach respective values 4 per cent and 0.04 .

The coefficients and pitching derivatives about the mid-root-chord axis are given for four of the sweptback tapered wings in Tables 38, 39, 40, 45 and 48. The typical effect of $m$ is illustrated in Fig. 13 by curves of the damping derivatives against axis position for Planform 10 at $M=0.8$. The factors such as $\beta^{-2}$ inside the square brackets of the appropriate equations (32) may not improve convergence, and there is evidence in Table 45b to this effect ; nevertheless, with $N=4$ and $\bar{m}=95$ the curves in Fig. 13 for $m=11$ and $m=15$ are close enough to allay serious doubts. It remains to look more closely at the separate effects of $m$ as collocation parameter and rounding parameter, and the results for Planform 11 in Tables 48 are used for this purpose in Section 6.

### 4.5. Slender Wings.

Let $s(x)$ be the local semi-span of a slender planform. Then, provided that the gradient

$$
d s / d x=s^{\prime}(x) \geqslant 0,
$$

the trailing edge is unswept and the incidence is uniform, slender-wing theory gives a load distribution

$$
\begin{equation*}
\frac{\Delta C_{p}}{\alpha}=\frac{4 s(x) s^{\prime}(x)}{\left[\{s(x)\}^{2}-y^{2}\right]^{1 / 2}} . \tag{36}
\end{equation*}
$$

Planforms 13 and 14 are complete delta wings of contrasting aspect ratios 1.5 and 0.0001 . In the latter case equation (36) is applicable, but $\Delta C_{p}$ remains non-zero along the trailing edge $x=c_{r}$. Thus the assumed loading in equation (15), which behaves like $0\left(c_{r}-x\right)^{1 / 2}$, is incorrect for all $\eta$. The slender gothic Planform 15 has been chosen to have

$$
\begin{equation*}
\frac{s(x)}{s}=1-\left(1-\frac{x}{c_{r}}\right)^{3 / 2}, \tag{37}
\end{equation*}
$$

so that equation (15) is no longer violated at the trailing edge when $\alpha$ is constant. In this case the singularities in chordwise loading at the leading and trailing edges are consistent with Multhopp's theory, except at the leading apex.

Steady-flow solutions for these three wings are found in Tables 16 to 18. In Table 16 the not-so-slender wing shows good convergence with respect to $q$ everywhere and with respect to $N$ away from the tip. Table 17 reveals poorer convergence in both respects when $A=0.0001$. Solutions for the slender gothic planform converge much better with respect to $N$, as demonstrated by the values of $\lambda_{0}$ in Tables 17 and 18 , but no satisfactory solutions could be obtained for $q>6$, as there appears to be a sudden ill-conditioning of the equations. Fortunately there is exact theory (Ref. 8) with which to compare solutions with $m=11$ and $q=6$ in the table below.

| Solution | Slender delta wing |  | Slender gothic wing |  |
| :---: | :---: | :---: | :---: | :---: |
|  | $C_{L} / A$ | $x_{a c} / \bar{c}$ | $C_{\dot{L}} / A$ | $x_{a c} / \bar{c}$ |
| $N=2$ | 1.4931 | 1.2318 | 1.5755 | 0.9339 |
| $N=3$ | 1.5400 | 1.3331 | 1.5681 | 0.9296 |
| $N=4$ | 1.5579 | 1.3189 | 1.5728 | 0.9290 |
| Exact | 1.5708 | 1.3333 | 1.5708 | 0.9167 |

These overall aerodynamic characteristics are inaccurate by comparison with the corresponding table for the circular planform in Section 4.2, but this is perhaps to be expected in view of the sharp central kinks.

The calculated local aerodynamic centres for the delta wing $(A=1.5)$ in Table 32a show rather poorer convergence with respect to $N$ than with respect to $q$, but would meet normal practical requirements. Tables 32 b and 32 c include the exact values for the slender delta wing

$$
\begin{equation*}
X_{a c}=\frac{1}{1-\eta}\left[\frac{1}{2}-\eta+\frac{\eta^{2} \operatorname{sech}^{-1} \eta}{2\left(1-\eta^{2}\right)^{1 / 2}}\right] \tag{38}
\end{equation*}
$$

and for the slender gothic wing

$$
\begin{equation*}
X_{a c}=\frac{3}{2\left(1-\xi_{1}\right)\left(1-\eta^{2}\right)^{1 / 2}} \int_{\xi_{1}}^{1} \frac{\left(\xi-\xi_{1}\right)(1-\xi)^{1 / 2}\left[1-(1-\xi)^{3 / 2}\right]}{\left[\left\{1-(1-\xi)^{3 / 2}\right\}^{2}-\eta^{2}\right]^{1 / 2}} d \xi \tag{39}
\end{equation*}
$$

where $\xi_{1}=1-(1-|\eta|)^{2 / 3}$. These are derived from equation (36) with $s(x)=s x / c_{r}$ and from equation (37) respectively. The spanwise distributions are drawn in Fig. 14 for $N=2,3$ and 4 . Although the solutions
become unreliable close to the tip, the results for both slender wings in the range $0.5<\eta<0.9$ approach the exact curve as $N$ increases. Near the centre the comparisons are less convincing; the delta wing shows poor convergence, and $X_{a c}$ at $\eta=0$ for the gothic wing appears to converge to a value 0.424 instead of the exact 0.4.

The central chordwise loadings on the two delta wings are plotted in Fig. 15. The trailing-edge condition is seen to have a dominant effect on the convergence with respect to $N$. Such detailed aerodynamic characteristics demonstrate the wide gulf between the slender-wing and lifting-surface theories. Since Planform 13 is nearly as slender as planforms are likely to become, the divergence in the upper diagram is academic, but so also may be the slender-wing theory in this context.

Garrick's ${ }^{8}$ theory for oscillations of low frequency is formulated for pitching motion in Appendix III of Ref. 20. Under the same conditions as equation (36) it can be shown that

$$
\left.\begin{array}{l}
-z_{\theta}=\frac{1}{4} \pi A \\
-m_{\theta}=\frac{1}{4} \pi A\left[\frac{c_{r}-x_{0}}{\bar{c}}-\frac{c_{r}}{\bar{c}} \int_{0}^{1}\left(\frac{s(x)}{s}\right)^{2} d\left(\frac{x}{c_{r}}\right)\right] \\
-z_{\dot{\partial}}=\frac{1}{4} \pi A\left[\frac{c_{r}-x_{0}}{\bar{c}}+\frac{c_{r}}{\bar{c}} \int_{0}^{1}\left(\frac{s(x)}{s}\right)^{2} d\left(\frac{x}{c_{r}}\right)\right]  \tag{40}\\
-m_{\dot{\theta}}=\frac{1}{4} \pi A\left[\frac{c_{r}-x_{0}}{\bar{c}}\right]^{2}
\end{array}\right\} .
$$

Although negative damping is never predicted, $-m_{\theta}$ falls to zero when the pitching axis coincides with the trailing edge. Now

$$
\begin{aligned}
& \frac{c_{r}}{\bar{c}}=2 \text { and } \int_{0}^{1}\left(\frac{s(x)}{s}\right)^{2} d\left(\frac{x}{c_{r}}\right)=\frac{1}{3} \quad \text { for the delta wing, } \\
& \frac{c_{r}}{\bar{c}}=\frac{5}{3} \text { and } \int_{0}^{1}\left(\frac{s(x)}{s}\right)^{2} d\left(\frac{x}{c_{r}}\right)=\frac{9}{20} \text { for the gothic wing, }
\end{aligned}
$$

and hence the picthing derivatives are easily evaluated. Coefficients from the collocation solutions are given for the three wings in Table 41, where the delta wing ( $A=1.5$ ) is seen to provide excellent convergence with respect to $q$ and $N$. The derivatives, calculated from equations (32) for the mid-root-chord axis in Table 46, show good convergence with respect to $N$ for the gothic wing, but not for the slender delta wing. Such is the effect of violating the condition of zero loading at the trailing edge. It is well summarized in Fig. 16 by the curves of $-m_{\theta} / A$ against $x_{0} / c_{r}$. The discrepancies between $N=4$ and exact theory are more than twenty times greater for the delta than for the gothic planform.

### 4.6. Wings with Curved Tips.

In Section 3.1 the lift slope and centres of lift of Planform 16 are used to illustrate a case in which the previous version of Multhopp's theory ( $q=1$ ) is in serious error. Moreover, Fig. 2 shows adequate convergence of overall forces with respect to the parameters $m, N$ and $q$. From the full solutions in Tables 20 and 21 for this wing at $M=0$ the local convergence is less satisfactory, especially in the region of the
curved tip. Associated features in the last three columns of Table $21(q=8)$ are the irregular spanwise distributions of $\mu_{n}, \kappa_{n}$ and $\lambda_{n}$, which can be attributed partly to the high sweepback ( $\Lambda=60^{\circ}$ ) and partly to the curved tip. In Table 22 the same features are found for Planform 17, another curved-tipped wing of slightly lower sweepback $\left(\Lambda=55^{\circ}\right)$ but at $M=0.8$. Here the lift slope with $m=11$ and $N=3$ falls by over 10 per cent as $q$ is increased from 1 to 8 . Attention is also drawn to the third and last solutions in Table 22, which differ only in the amount of central rounding; this is seen to influence the lift slope by 2 per cent and the local lift at $\eta=0$ by 8 per cent. The behaviour of the calculated $\partial C_{L} / \partial \alpha$ is plotted in the upper diagrams of Fig. 17, which demonstrate the effect of $q$ and suggest that the aerodynamic effect of the artificial rounding may need to be taken into account (Section 6).

There are eleven solutions with $N=3$ for Planform 17 in low-frequency pitching motion at $M=0.8$. The coefficients in Table 42 and the derivatives for the mid-root-chord axis in Table 47 show a marked effect of $q$ with satisfactory convergence, but there are considerable differences between the five results with $\bar{m}=95$ as the rounding and number of collocation sections are changed. The pitching damping about the axis $x_{0}=1 \cdot 5 \bar{c}$ just forward of the aerodynamic centre is plotted against $(\bar{m}+1)$ and $(m+1)$ in the lower part of Fig. 17. By increasing the parameter $q$ the discrepancies are reduced from 30 per cent ( $\bar{m}=m=11$ ) to $\pm 3$ per cent.

A peculiarity of curved tips is the behaviour of local aerodynamic centres in Tables 33 and 34. Previous solutions with $q=1$ had indicated a rapidly falling value of $X_{a c}$ as $\eta \rightarrow 1$ in common with the accepted characteristic of sweptback wings of non-zero tip chord, viz., Fig. 8. Spanwise distributions of $X_{a c}$ for the two curved-tipped wings are drawn in Fig. 18, where the upper diagram for Planform 17 shows a marked effect of $q$ such that the fall in $X_{a c}$ virtually disappears; there remains, however, the irregular waviness already noted. The lower diagram supports the progressive effect of $q$ on $X_{a c}$ by experimental data from Ref. 34 calculated from observed pressure distributions on two half-models of Planform 16 with different aerofoil thickness. Apart from the slender delta wing (Section 4.5), planforms with curved tips have presented the greatest difficulties regarding convergence. They have, nevertheless, proviled convincing examples of the need for the improved programme of Ref. 18 and some experimental confirmation of its success.

## 5. Criteria for Selecting $m, N$ and $\bar{m}$.

The preceding sub-sections have demonstrated that the rate of convergence of solutions by the Algol programme of Ref. 18 is highly dependent on the type of planform. From the wide range of results available it should be possible to recommend a suitable set of values of the parameters $m, N$ and $\bar{m}$ for other planforms, but discretion is needed according to the scope of the aerodynamic quantities to be evaluated and the required accuracy.

The difficulty in choosing the number of collocation sections is that in the standard procedure for kinked planforms the odd integer $m$ has the added role of defining the artificial central rounding. Where this complication does not arise, i.e. for Planforms $1,2,3,4$ and $6,(m+1)$ can safely be taken below the value $4 A \sec \Lambda_{1}$ recommended as a minimum in Section 2.4 of Ref. 18, unless accurate results are required close to the wing tip. It is probably best to relate the choice of $m$ to the length of the trailing edge and, in view of the factors $\beta^{-2}$ in the square brackets of the last two of equations (32), not to reduce its value in compressible flow. In general, the recommendation of Ref. 18 should be followed and the number of collocation sections should satisfy the condition

$$
\begin{equation*}
m+1 \geqslant 4 A \sec \Lambda_{1} \tag{41}
\end{equation*}
$$

where for curved trailing edges $\sec \Lambda_{1}$ may be regarded as the length of the trailing edge as a fraction of the span. However, it is undesirable to take $m<11$, and this is the recommended minimum value whenever $A \sec \Lambda_{1}<3$. From Section 6 it will appear that, when artificial rounding is necessary, the standard $y_{1}$ in equations (18) to (20) should be replaced by

$$
\begin{equation*}
y_{2}=s \sin \frac{2 \pi}{m+1} . \tag{42}
\end{equation*}
$$

The results then involve smaller collocation error but need some allowance for the rounding itself.
An increase in the number of chordwise terms causes slower convergence with respect to $\bar{m}$. It is therefore desirable to choose the smallest value of $N$ that ensures theoretical data to the required accuracy. In practice the choice rests between $N=3$ and $N=4$. For the simple mode of rigid pitching oscillation there is little evidence in Tables 43 to 47 to suggest that appreciable errors would result from using $N=3$. Only in the case of the slender gothic wing in Table 46 c would $N=4$ seem to be overwhelmingly advantageous. In steady flow at uniform incidence, however, it is essential to take $N=4$ when the chordwise loading is to be calculated near a tip or a central kink. A glance at the magnitude of $\lambda_{n}$, when it appears in Tables 3 to 22, gives the best indication of the importance of the fourth chordwise term. At the central section, for example, it is only for wings of leading-edge sweepback tan $\Lambda_{0} \geqslant \beta$ that $\left|\lambda_{0}\right|$ exceeds 0.01 . For applications to more complicated oscillatory modes or camber distributions the four terms may prove inadequate and the method of Ref. 18 must be used with discretion.

In the course of the present work convergence with respect to $\bar{m}$ or $q$ has naturally been a major preoccupation. One criterion embracing a wide range of planforms is that the lift slope $\partial C_{L} / \partial \alpha$ should be within $\frac{1}{2}$ per cent of its value for the highest attainable value of $q$. The upper part of Fig. 19 shows for ten planforms the roughly estimated values of the quantity

$$
\frac{\bar{m}+1}{\beta A} \sin ^{2}\left(\frac{\pi}{2 N+1}\right)=\frac{q(m+1)}{\beta A} \sin ^{2}\left(\frac{\pi}{2 N+1}\right)
$$

above which this is achieved. The critical values depend to some extent on $N$, but the values are mainly for $N=3$ and lie reasonably close to a curve against $\beta^{-1} \tan \Lambda_{\frac{1}{2}}$, where $\Lambda_{\frac{1}{2}}$ is the angle of mid-chord sweepback. In producing a criterion for selecting $\bar{m}$, the compressibility factor is retained in the sweepback but, to ensure extra accuracy of the coefficients in equations (32), it is omitted in the aspect ratio. The full curves in the lower part of Fig. 19 give the corresponding critical values of $(\bar{m}+1) / A$ for $N=3$ and 4 and offer one lower limit to $\bar{m}$ as an alternative to the tentative equation (5). Another consideration from Sections 4.1 and 4.4 is that there is usually a substantial improvement in a solution when $q$ is increased from 1 to 2 , and $q=2$ should be regarded as a minimum value. It therefore follows from the recommended choice of $m$ that

$$
\left.\begin{array}{l}
\bar{m}+1 \geqslant 24  \tag{43}\\
\bar{m}+1 \geqslant 8 A \sec \Lambda_{1}
\end{array}\right\}
$$

which for $N=3$ will usually be more restrictive than the condition set in Fig. 19.
The following table lists the minimum odd values of $\bar{m}$ from the conditions (43) and any larger values that may be required by equation (5) or Fig. 19.

| Planform |  |  |  |  | Minimum $\bar{m}(N=3)$ |  |  |  |  |
| ---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| No. | $A$ | $A \sec \Lambda_{1}$ | $\tan \Lambda_{\frac{1}{2}}$ | Eqn. (43) | Eqn. (5) | Fig. 19 <br> $M=0$ | Fig. 19 <br> $M=0.8$ |  |  |
| 2 | 4.00 | 4.00 | 0 | 31 | 43 | - | - |  |  |
| 3 | 8.00 | 8.00 | 0 | 63 | 85 | - | - |  |  |
| 5 | 4.33 | 4.48 | 0 | 35 | 47 | - | - |  |  |
| 7 | 4.00 | 5.66 | 1.00 | 45 | 61 | - | 61 |  |  |
| 9 | 2.83 | 3.37 | 1.00 | 27 | 35 | 29 | 43 |  |  |
| 10 | 1.45 | 1.53 | 0.58 | 23 | - | - | - |  |  |
| 11 | 2.00 | 2.24 | 1.12 | 23 | 23 | - | 33 |  |  |
| 12 | 8.00 | 10.54 | 0.95 | 85 | 111 | - | 115 |  |  |
| 13 | 1.50 | 1.50 | 1.33 | 23 | - | - | $(31)$ |  |  |
| 16 | 3.90 | 7.80 | 1.73 | 63 | 83 | - | $?$ |  |  |
| 17 | 3.56 | 6.20 | 1.43 | 49 | 65 | - | $(79)$ |  |  |

Equation (5) usually overrides conditions (43) and can be recommended for $M=0$. The larger values of $\bar{m}$ from Fig. 19 for $M=0.8$ are thought to be essential. For the tapered sweptback wings of moderately small aspect ratio the pitching damping derivatives tend to converge more slowly than the lift slope on which Fig. 19 is based. Table 45a for Planform 9 suggests that $\bar{m}=63$ is desirable when $M=0.8$. This is met by modifying conditions (43) to become

$$
\left.\begin{array}{l}
\bar{m}+1 \geqslant 24 / \beta^{2}  \tag{44}\\
\bar{m}+1 \geqslant 8 A \sec \Lambda_{1}
\end{array}\right\}
$$

Then equations (5) and Fig. 19 only enter into consideration when both aspect ratio and sweepback are moderately high or when in applications to detailed load distributions in steady flow it is necessary to take $N=4$. The following sets of maximum permissible values of $m, q$ and $\bar{m}$ will then apply.

| $m$ | 11 | 15 | 21 | 27 |
| :---: | ---: | ---: | ---: | ---: |
| $q$ | 14 | 8 | 4 | 2 |
| $\bar{m}$ | 167 | 127 | 87 | 55 |

The tables in Section 1 of Ref. 18 indicate other upper restrictions on $m, N$ and $q$, which are imposed to keep within the capacity of the KDF9 computer and an arbitrary maximum running time of 45 minutes. For planforms of high aspect ratio where these restrictions prohibit the use of the recommended values of $m, N$ and $\bar{m}, N$ should be reduced to 3 or ( $m+1$ ) should be lowered from $4 A \sec \Lambda_{1}$ until a satisfactory value of $\bar{m}$ can be accommodated.

## 6. Central Rounding of Sweptback Planforms.

Earlier sections have foreshadowed the need to study the influence of the central rounding on the solutions. It may be asked what happens when the rounding in equations (18) to (20) is increased, reduced or removed. It may be wondered whether such a study can shed light on the discrepancy between direct and reverse flow in the lower half of Fig. 9. In Figs. 11, 12 and 17 the rounding has been kept constant while the number of collocation sections has been increased, and crucial uncertainty lies in the aerodynamic influence of the rounding itself. It remains to clarify these three matters and to re-interpret certain of the
theoretical data already discussed.
There are four planforms for which the rounding has been systematically varied without changing the collocation sections and spanwise integration points. The solutions at steady unit incidence in Tables 9, 14 and 19 include a fixed value of $m$ to denote the number of collocation sections and a variable $m$ to define $y_{1}$ in equation (18); in Table 9, for example, $m=\infty$ denotes zero rounding and $m=7$ is virtually twice the standard rounding $m=15$, and their respective effects are to reduce $C_{L}$ by $7 \frac{1}{2}$ per cent and to increase it by 2 per cent. Naturally there are marked changes in the loading functions $\gamma_{0}, \mu_{0}, \kappa_{0}$ and $\lambda_{0}$ at the centre section. For the slender gothic wing there is no difficulty in computing the exact central chordwise loading from equation (36)

$$
\begin{equation*}
\Delta C_{p} / \alpha=4 s^{\prime}(x) \text { at } y=0 \tag{45}
\end{equation*}
$$

so as to include the effect of the rounding. Fig. 20 shows full curves from exact theory with the standard $m=11$ rounding and also with $m=5$ and $m=23$, to compare with the distributions when $\gamma_{0}, \mu_{0}$ and $\kappa_{0}$ from Table 19 are substituted into equation (15). There is a remarkable diminution in collocation error with twice the standard rounding, and as decisive a worsening when the standard rounding is halved. It follows from equation (45) that the distance of the local aerodynamic centre from the trailing edge is precisely the geometric mean chord. Referred to the actual root chord $c_{r}$,

$$
\begin{equation*}
X_{a c}=1-\frac{S^{\prime}}{2 s c_{p}} \tag{46}
\end{equation*}
$$

where $S^{\prime}$ is the area of the rounded planform. The top left diagram of Fig. 21 compares the result

$$
\begin{equation*}
X_{a c}=\frac{1}{c_{r}}\left[x_{l 0}+c_{0}\left(\frac{1}{4}-\frac{\mu_{0}}{\gamma_{0}}\right)\right] \tag{47}
\end{equation*}
$$

from the solutions in Table 19 with equation (46) and shows that with twice the standard rounding $(m+1=6)$ the collocation and rounding errors are nearly equal. Against the same diagrammatic scale of the rounding parameter ( $m+1$ ), Fig. 21 shows for each of the four wings the central $X_{a c}$ and the ratio of $C_{I}$ to its value with the standard rounding. Especially for Planforms 7 and 9 with sweptback trailing edges, there is no sign of convergence at either end of the scale. The conclusion is reached that solutions with less than the standard rounding are useless, while those with greater rounding may need some correction to offset its genuine aerodynamic influence.

Fig. 7 of Ref. 36 indicates excellent agreement between damping derivatives $-z_{\theta}$ and $-m_{\theta}$ against pitching axis calculated from direct-flow and reverse-flow solutions for Planform 11 at $M=0.781$. These calculations correspond to $m, N, q=15,3,1$ in the present method and are now seen to give misleading satisfaction. The effects of $q$ in direct and reverse flow are given by coefficients in Table 39, by derivatives in Table 48 and graphically in Fig. 22. Although both solutions converge with respect to $q$, they diverge from each other until with $q \geqslant 4$ there are constant discrepancies of 0.1 in $z_{\dot{\theta}}$ and 0.03 in $m_{\dot{\theta}}$. These discrepancies are repeated when the number of chordwise terms is increased to $N=4$. Spanwise collocation error due to the irregularity of the planform with $m=15$ rounding is suspected, and further solutions have been obtained with the same rounding but $m, N, q=31,3,2$. The points ( $O$ and $X$ ) for $\bar{m}+1=64$ in Fig. 22 show that the discrepancies between direct and reverse flow are reduced by the factor 0.18 to a satisfactory level. An even better result can be achieved with $m, N, q=15,3,6$ and the rounding used in Ref. 23 which amounts to equations (19) with a different square bracket, viz.,

$$
\left.\begin{array}{l}
x_{l}(y)=x_{l}\left(y_{1}\right)\left[\frac{1}{3}+\left(\frac{|y|}{y_{1}}\right)^{2}-\frac{1}{3}\left(\frac{|y|}{y_{1}}\right)^{3}\right]  \tag{48}\\
c(y)=c_{r}+\left[\frac{1}{3}+\left(\frac{|y|}{y_{1}}\right)^{2}-\frac{1}{3}\left(\frac{|y|}{y_{1}}\right)^{3}\right]\left\{c\left(y_{1}\right)-c_{r}\right\}
\end{array}\right\}
$$

The lower order of the polynomial in $|y| / y_{1}$ gives rounded leading and trailing edges with larger displacement and smaller curvature. The only misgiving is that the displacement may be influencing the answer and that the effect, though apparently small in Fig. 22, may be important for more highly swept trailing edges.

An attempt has been made to estimate the genuine effect of the rounding by considering only solutions in which the standard rounding is doubled. Thus $y_{2}$ in equation (42) is used in place of $y_{1}$ in equations (18) to (20). The ratio of the displacement of the leading edge to the root chord

$$
\begin{equation*}
\xi_{0}=\frac{x_{l 0}}{c_{r}}=\frac{y_{2} \tan \Lambda_{0}}{6 c_{r}} \tag{49}
\end{equation*}
$$

is taken as a measure of the rounding. Such solutions are available for Planforms 7, 9, 13 and 16 each with two different roundings and will be found in Tables 9,14 and 49. Corresponding values of overall forces, spanwise loading and local aerodynamic centres are presented in Table 50. For the Planform 7 of constant chord there are three solutions in Table 9 with $N=3$ and the following results are obtained.

| Rounding $m, N, q$ $\xi_{0}$ | $\begin{aligned} & m=15 \\ & 31,3,2 \\ & 0 \cdot 0650 \end{aligned}$ | $\begin{aligned} & m=11 \\ & 23,3,4 \\ & 0.0863 \end{aligned}$ | $\begin{aligned} & m=7 \\ & 15,3,6 \\ & 0 \cdot 1276 \end{aligned}$ |
| :---: | :---: | :---: | :---: |
| $C_{L}$ | $3 \cdot 0042$ | 3.0080 | 3.0215 |
| $\bar{\eta}$ | $0 \cdot 4653$ | 0.4649 | $0 \cdot 4640$ |
| $x_{a c} / \bar{c}$ | $1 \cdot 1748$ | $1 \cdot 1743$ | 1.1764 |
| $C_{L L}$ at $\eta=0$ | 3.0460 | 3.0740 | $3 \cdot 1322$ |
| $X_{a c}$ at $\eta=0$ | $0 \cdot 4034$ | $0 \cdot 4170$ | $0 \cdot 4464$ |

Since the values tabulated above are roughly linear in $\xi_{0}$, it is permissible to think in terms of gradients

$$
\frac{1}{C_{L}} \frac{\partial C_{L}}{\partial \xi_{0}}, \frac{\partial \bar{\eta}}{\partial \xi_{0}}, \frac{\partial}{\partial \xi_{0}}\left(\frac{x_{a c}}{\bar{c}}\right), \frac{1}{C_{L L}} \frac{\partial C_{L L}}{\partial \xi_{0}}, \frac{\partial X_{a c}}{\partial \xi_{0}},
$$

and these are estimated for the four wings and plotted against $A \tan \Lambda_{1}$ in Fig. 23. To the rough accuracy now envisaged the straight lines adequately represent the known data and can be used to re-interpret some of the discrepancies that have already arisen.
First we consider Fig. 2 in relation to the appreciably different results in Table 50d with doubled rounding and small collocation error. When the overall forces in Table 50d for the $m=15$ rounding are corrected by subtraction of the contributions from Fig. 23 with $\xi_{0}=0.103$ and $A \tan \Lambda_{1}=6 \cdot 75$, the final values are

$$
\left.\begin{array}{rl}
\partial C_{L} / \partial \alpha & =2.3500[1-(0.18 \times 0.103)]
\end{array}=2.306, ~=0.4717\right\}
$$

It may be concluded that in Fig. 2 there are opposing effects of collocation error and rounding error, so that the standard results with sufficient $\bar{m}$ are better than would be expected.
Next there is the discrepancy in pitching damping between direct and reverse flow for Planform 7 in Fig. 9. There are some further calculations for this wing with twice the standard rounding in Table 51,
which illustrate the transformation in equations (33) and (34) from coefficients $\bar{I}_{L r},-\bar{I}_{m r}$ and $-\bar{I}_{m r}^{*}$ for the reversed wing to $I_{t r .}-I_{m r}$ and $-I_{m r}^{*}$ from reverse flow. The worst discrepancies in $m_{i,}$ for the rearward axes are reduced from 10 per cent to an acceptable 2 por cent. Tables 51a and 51c sugew that the pitching derivatives are not linear in $\xi_{0}$, but that the corrections to allow for the smaller roundings are negligible in this case.

From the solution in the last column of Table 15 and the last row of Table 31 we may comment on the results in Figs. 11 and 12 for Planform 12. Since $\xi_{0}=0.0988$ and $A \tan \Lambda_{1}=6.86$, the final estimated theoretical values of total and local loads at $\eta=0$ are

$$
\begin{aligned}
& \partial C_{L} / \partial \alpha=3.7634[1-(0.18 \times 0.0988)]=3.696 \\
& x_{a c} / \bar{c}=2.1745+(0.055 \times 0.0988) \quad=2.180 \\
& c C_{L L} / \bar{c} C_{L}=1.0981 \times \frac{1-(0.71 \times 0.0988)}{1-(0.18 \times 0.0988)}=1.040 \\
& X_{a c}=0.4214-(0.85 \times 0.0988) \quad=0.337
\end{aligned}
$$

The lift slope and aerodynamic centre in Fig. 11, corresponding to $\bar{m}=95$ and the standard rounding, are again fairly consistent with the new values. In the case of the lift slope the collocation and rounding errors due to $m$ almost cancel, while the rounding correction to $x_{a c} / \bar{c}$ takes it half-way back to its value with the standard rounding. The load grading $\left(c C_{L L} / \bar{c} C_{L}\right)$ at $\eta=0$ in Fig. 12 is not improved by considering collocation error alone as the rounding error is now estimated to be larger and of opposite sign; the new value is fairly consistent with the trend of the full curve for $\bar{m}=95$ and the standard rounding. It is perhaps premature to discuss the local $X_{a c}$ at the centre section, but the facts suggest that Fig. 12 is quite misleading and that the rapid increases as $\eta \rightarrow 0$, plotted in Fig. 8 for example, are grossly exaggerated. Moreover, there is experimental evidence for this wing in Fig. 14 of Ref. 32 to support the new value $X_{a c}=0.337$.

The next discrepancy to consider is that for the slender gothic planform at $\eta=0$ in Fig. 14. The solution in Table 19 with twice the standard rounding gives the local $X_{a c}=0.4110$ when $\xi_{0}=0.0617$. The corrected value is

$$
X_{a c}=0.4110-(0.28 \times 0.0617)=0.394
$$

in better agreement with the exact value 0.4 than the result $X_{a c}=0.424$ in Fig. 14.
It is suggested in Section 4.6 that the behaviour of $\partial C_{L} / \partial \alpha$ in the top right diagram of Fig. 17 is evidence that the aerodynamic effect of the artificial rounding may need to be taken into account. The solution with twice the standard rounding and $\zeta_{0}=0.0977$ for Planform $17\left(A \tan \Lambda_{1}=5.08\right)$ at $M=0.8$ is now corrected to give

$$
\partial C_{L} / \partial \alpha=2.7918[1-(0.13 \times 0.0977)]=2.756,
$$

a value in keeping with the trend of the results labelled $\bar{m}=95$ in Fig. 17.
A final instance of the importance of considering both collocation and rounding error concerns the value of $X_{a c}$ at $\eta=0.195$ in the lower diagram of Fig. 18. The result in Table 50d for the smaller doubled rounding is now corrected to give

$$
X_{a c}=0.2771-(0.08 \times 0.103)=0.269
$$

which is seen to be in better agreement with experiment than the standard solution with $m, N, q=15,4,8$.

## 7. Concluding Remarks.

(1) A parallel investigation is reported in Ref. 39, where Planforms 1, 4, 6 and 9 in steady incompressible flow are treated by the methods of Refs. 18, 23 and 24 . By comparison with the present investigation a higher degree of accuracy is sought and remarkably good agreement is found between the three methods. There is no doubt about the increasing superiority of Ref. 23 for wings of higher aspect ratio and of Ref. 24 when much larger numbers of chordwise terms are necessary.
(2) The present investigation establishes that large errors can result from previous extensions of the steady-flow theory of Ref. 19 or the low-frequency theory of Ref. 20 to three and four chordwise terms. The refinements in Ref. 18 reduce these errors to meet practical requirements in theoretical spanwise loading, local aerodynamic centres and oscillatory pitching derivatives.
(3) The properties of numerical convergence differ throughout the range of planforms. Rectangular wings require remarkably few, say $A=$ aspect ratio, collocation sections on the half-wing. For more general planforms, provided the leading and trailing edges are smooth and of low curvature, 2 A collocation sections on the half-wing are adequate. The central kink of a sweptback wing leads to a situation in which the balance between artificial rounding and number of collocation sections becomes crucial, with further complication in the convergence of wing loading near curved tips.
(4) To define a calculation for a particular planform and Mach number, the following choice of parameters is recommended:

$$
m+1 \geqslant 4 A \sec \Lambda_{1},
$$

where $\sec \Lambda_{1}$ is generalized to be the length of the trailing edge as a fraction of the span.

$$
\left.\begin{array}{l}
N=3 \quad \text { for calculations of pitching derivatives unless } \beta A \leqslant 1, \text { say }, \\
N=4 \quad \text { for elastic modes of oscillation or detailed wing loading. } \\
q \geqslant 2 \quad \text { and related conditions } \\
\bar{m}+1 \geqslant 24 / \beta^{2} \\
\bar{m}+1 \geqslant 8 A \sec \Lambda_{1} \\
\bar{m}+1 \geqslant 2 A \sec \Lambda_{1} \operatorname{cosec}^{2} \frac{\pi}{2 N+1} \\
(\bar{m}+1) \quad \text { to satisfy Fig. } 19
\end{array}\right\}
$$

(5) Errors are likely to persist near a kinked centre section or crank and near a tip. For chordwise loading the maximum $N=4$ is inadequate locally if the kink is severe or the tip is too closely explored, but it should suffice elsewhere unless the camber or deformation of the wing warrants a larger value from twodimensional considerations. Checks by reverse flow have proved that a severe central kink must be given adequate rounding if collocation error is to be acceptable; the standard rounding in Ref. 18 falls short in this respect. If the leading-edge sweepback is of order 45 deg , then the doubled extent of rounding

$$
0<y<y_{2}=\sin \frac{2 \pi}{m+1}
$$

is recommended in place of equation (18) or, following Ref. 23, the rounding from equation (48) may be used.
(6) Fig. 23 has been prepared on the hypotheses that the doubled displacement of the leading edge

$$
\xi_{0} c_{r}=x_{l 0}=\frac{1}{6} y_{2} \tan \Lambda_{0}
$$

eliminates collocation error, and that the rounding itself introduces an aerodynamic effect proportional to $\xi_{0}$. Thus the solutions with doubled rounding may be corrected roughly for rounding error which is quite as important as the collocation error with the standard rounding. Section 6 includes several examples to suggest that the standard solutions with both collocation and rounding errors are closer to the true solution for the planform with leading apex than the others with only rounding error; local aerodynamic centres from the latter, corrected for rounding error, are found to lie closer to exact theory or experiment. (7) The method of Ref. 18 and the present results have been applied or developed along the following lines:
(i) As suggested in Section 1, the same principles now under discussion apply equally to certain subsonic theories with general frequency parameter and have led to the significant improvements in Ref. 40.
(ii) The present low-frequency method has been extended to treat slowly oscillating part-span control surfaces, in particular the derivatives of hinge moment (Ref. 41).
(iii) The AGARD Manual on Aeroelasticity is to include an extra chapter, in which the results of numerous oscillatory theories are compared for wings including Planforms 4, 5, 10 and 11 (Ref. 42).
(iv) The influence of central rounding on local loading is so large that it requires more systematic study; the few solutions with doubled rounding in Tables $9,14,15,19,22$ and 49 are suitable for further analysis.
(v) Half-models of Planforms 8, 9, 12, 16 and 17 without twist or camber or fuselage have been extensively pressure plotted, and theoretical solutions for these wings can be extended to include effects of aerofoil thickness.

## Acknowledgements.

The author acknowledges the assistance of Mrs. S. Inch of the Aerodynamics Division, N.P.L., who has been responsible for the preparation of data tapes and the tabulated results. She and Mrs. S. Lucas have shared the task of numerical analysis and have helped to prepare the illustrations. Acknowledgments are also due to the operators of the KDF9 computer in the Central Computer Unit, N.P.L.

## LIST OF SYMBOLS

| $A$ | Aspect ratio $; 2 \mathrm{~s} / \bar{c}$ |
| :---: | :---: |
| $c$ | Local chord |
| $\bar{c}$ | Geometric mean chord; $S / 2 s$ |
| $c_{n}$ | Local chord at station $n$ including any artificial rounding |
| $c_{r}$ | Root chord |
| $C_{L}$ | Lift coefficient $;$ lift $/ \frac{1}{2} \rho U^{2} S$ |
| $C_{L L}$ | Local lift coefficient; local lift $/ \frac{1}{2} \rho U^{2} c$ |
| $C_{m}$ | Nose-up pitching moment about root leading edge $/ \frac{1}{2} \rho U^{2} S \bar{c}$ |
| $C_{p}$ | Pressure coefficient; $\Delta C_{p}=$ pressure difference $/ \frac{1}{2} \rho U^{2}$ |
| $I_{L r}, I_{m r}$ | Lift and pitching-moment coefficients in equations (16) |
| $\bar{I}_{L r}, \bar{I}_{m r}$ | Equivalent of $I_{L r}, I_{m r}$ for reversed planform |
| $I_{m r}^{*}, \bar{I}_{m r}^{*}$ | Second moment coefficient in equation (17) for direct, reversed planform Kernel function |
| $l$ | Non-dimensional load distribution; $\Delta C_{p}$ |
| 1 | Complex load distribution from expression (1) |
| $l_{r}$ | Loading $l$ corresponding to $\alpha=\alpha_{r}$ in equations (13) and (14) |
| $m$ | Number of collocation sections; rounding parameter in equation (18) |
| $\bar{m}$ | Number of spanwise integration points; $q(m+1)-1$ |
| $m_{\theta}, m_{\theta}$ | Oscillatory pitching-moment derivatives in equation (31) |
| M | Mach number of free stream |
| $n$ | Subscript or integer denoting loading station in equation (11) |
| $N$ | Number of chordwise functions or collocation points |
| $q$ | Factor; ( $\bar{m}+1) /(m+1)$ |
| - | Subscript or integer denoting incidence in equations (13) and (14) |
| $s$ | Semi-span of wing |
| $s(x)$ | Local semi-span of wing |
| $S$ | Area of planform |
| $t$ | Time |
| $U$ | Velocity of free stream |
| $\begin{array}{r} x, y \\ x^{\prime}, y^{\prime} \end{array}$ | Rectangular co-ordinates referred to root leading edge |
| $x_{0}$ | Location of pitching axis |
| $x_{a c}$ | Aerodynamic centre referred to $\bar{c} ;-C_{m} / C_{L}$ |
| $x_{l}$ | Ordinate of leading edge |

## LIST OF SYMBOLS-continued

$x_{\text {ln }} \quad$ Ordinate of leading edge at station $n$ including any artificial rounding
$X_{a c} \quad$ Local aerodynamic centre referred to leading edge in equation (23)
$y_{1}, y_{2} \quad$ Semi-span of artificial rounding $; s \sin \frac{\pi}{m+1}, s \sin \frac{2 \pi}{m+1}$
$z \quad \frac{1}{2}(m-1)$
$\bar{z} \quad$ Complex upward displacement of wing surface
$z_{\theta}, z_{\theta} \quad$ Lift derivatives for pitching oscillations in equation (31)
$\alpha \quad$ Incidence of wing (radians)
$\alpha_{r} \quad$ Distribution of incidence in equations (13) and (14)
$\beta \quad$ Compressibility factor; $\left(1-M^{2}\right)^{1 / 2}$
$\gamma \quad$ Non-dimensional circulation; $\frac{1}{4} c C_{L L} / s$
$\gamma_{n} \quad$ First chordwise loading function in equation (10)
$\eta \quad$ Spanwise ordinate; $y / s$
$\bar{\eta} \quad$ Spanwise centre of pressure in equations (25) and (27)
$\theta \quad$ Spanwise parameter; $\cos ^{-1} \eta$
$\theta_{0} \quad$ Amplitude of pitching oscillation (radians)
$\kappa_{n} \quad$ Third chordwise loading function in equation (10)
$\lambda \quad c_{r} / \bar{c}$
$\lambda_{n} \quad$ Fourth chordwise loading function in equation (10)
$\Lambda \quad$ Angle of sweepback
$\Lambda_{\xi} \quad$ Local sweepback at chordwise position $\xi=0, \frac{1}{2}, 1$
$\mu_{n} \quad$ Second chordwise loading function in equation (10)
$v \quad$ Subscript or integer denoting collocation section in equation (7)
$\bar{v} \quad$ Frequency parameter; $\omega \bar{c} / U$
$\xi \quad$ Local chordwise position; $\left(x-x_{l}\right) / c$
$\xi_{0} \quad$ Leading-edge rounding parameter; $x_{10} / c_{r}$
$\rho \quad$ Density of free stream
$\phi \quad$ Chordwise parameter; $\cos ^{-1}(1-2 \xi)$
$\omega \quad$ Circular frequency of oscillation

Constant-Chord Wing ( $A=4, \Lambda=45^{\circ}, M=0$ ) with Double Rounding in Oscillatory Motion.
(c) Pitching derivatives $\left(x_{0}=0.5 \mathrm{c}\right)$

|  | Direct flow |  |  | Reverse flow |
| :---: | :---: | :---: | :---: | :---: |
| $m_{9} \mathrm{~N}, \mathrm{q}$ | $15,3,6$ | $23,3,4$ | $31,3,2$ | $31,3,2$ |
| $-z_{\theta}$ | 1.51076 | 1.50400 | 1.50212 | 1.50612 |
| $-m_{\theta}$ | 1.02181 | 1.01414 | 1.01357 | 1.00772 |
| $-z_{\theta}^{\circ}$ | 1.47462 | 1.45660 | 1.45411 | 1.44190 |
| $-m_{\theta}^{\cdot}$ | 1.46997 | 1.45847 | 1.45913 | 1.44535 |

Fig. 1. Convergence of local aerodynamic centres on rectangular wings with respect to $\bar{m}$ and $N$.

Fig. 2. Convergence of lift slope and centres of lift on a curved-tip wing with respect to $\bar{m}$ and $N$.

Fig. 3. Convergence of pitching derivatives for a constant-chord wing with hyperbolic leading edge.

Fig. 4. Convergence of pitching stiffness and damping with respect to $m$ for a sweepback wing of hieh asject ratio.

Fig. 5. Correlation of convergence with respect to $\bar{m}$ for rectangular wings in steady flow $(N=3)$.

Fig. 6. Convergence of aerodynamic centres of wings with streamwise symmetry from direct and reverse flow ( $M=0$ ).

Fig. 7. Convergence of pitching damping derivatives about axis of streamwise symmetry from direct and reverse flow.

Fig. 8. Effect of $m$ and $q$ on spanwise distributions of $X_{a c}$ for three constant-chord wings of aspect ratio $4(M=0)$.

FIG. 9. Pitching damping against axis position for sweptback wings of constant chord with and without central kink.

$\stackrel{\rightharpoonup}{n}$

Fig. 10. Effect of $q$ on lift slope and aerodynamic centre of an arrowhead wing in compressible flow

$$
(m=15) .
$$

Fig. 11. Convergence of lift slope and aerodynamic centre with respect to $m$ for a sweptback wing of high aspect ratio.

Fig. 12. Convergence of local lift and $X_{a c}$ at centre section of a sweptback wing of high aspect ratio.

Fig. 13. Effect of $m$ on damping derivatives against axis position for a sweptback wing of low aspect ratio at $M=0.8$.

Fig. 14. Effect of $N$ on spanwise distributions of $X_{a c}$ on slender delta and gothic wings ( $A=0.0001$ ).

Fig. 15. Effect of $N$ on central chordwise loadings of delta wings of aspect ratios $0 \cdot 0001$ and $1 \cdot 5$.

Fig. 16. Effect of $N$ on pitching damping against axis position for slender delta and gothic wings ( $A=0.0001$ ).

\&

Fig. 17. Convergence of lift slope and pitching damping on a curved-tipped wing at $M=0.8$ with respect to $\bar{m}$ and $m$.

Fig. 18. Effect of $q$ on spanwise distributions of $X_{a c}$ for two curved-tipped wings and comparison with experiment.

Fig. 19. Approximate criterion for selecting $\bar{m}$ for a given planform, Mach number and number of chordwise terms.

Fig. 20. Comparisons with exact theory of central chordwise loadings of a slender gothic wing with various amounts of rounding.

Fig. 21. Calculated effect of $m$ as a rounding parameter on central $X_{a c}$ and total lift of four
wings ( $M=0$ ).

Fig. 22. Convergence of pitching damping derivatives of an arrowhead wing with fixed rounding from direct and reverse flow.

Fig. 23. Approximate effect of rounding on total and locals loads from solutions for sweptback wings with twice the standing rounding.
