Reports and Memoranda No. 3653*
March, 1969

## Summary.

A comprehensive low-speed experiment on a three-dimensional turbulent boundary layer is described and the results are presented in detail. The flow caused by an obstruction placed in a thick two-dimensional boundary layer is investigated at a free-stream velocity of $200 \mathrm{ft} / \mathrm{s}$. The boundary-layer momentumthickness Reynolds numbers are approximately 50000.

The investigation is reported in two parts. This part is concerned with the area of the flow directly up-stream of the obstruction, which includes the axis of symmetry of the flow and extends down-stream as far as the saddle separation point and the adjacent boundary-layer separation lines. Part 2 is concerned with the flow to one side of the obstruction and the main characteristic of this region is that it contains a free-stream inflexion.

Referring to the area of the flow investigated in this part, it is shown that polar plots of the velocity vector through the boundary layer are well represented by Johnston's triangular model. The extension of the law of the wall to three dimensions is discussed. Simple extensions to three dimensions of existing methods of representing two-dimensional profiles, using Cole's wake function and Thompson's weighting function, are shown not to fit the data.

## 1. Introduction.

The development of three-dimensional turbulent boundary layers is of considerable interest since, in practice, the majority of boundary layers are of this type. The particular aspects of the flow which are of most interest at low speeds are probably the occurrence of three-dimensional separation, which for example causes the stalling of lifting bodies; the skin'friction field, from which the overall skin-friction drag can be determined, and the effective displacement, thickness which will be required to predict the pressure field about three-dimensional bodies. These requirements necessitate calculating the development of a three-dimensional boundary layer in a given pressure field up to separation and ideally beyond separation to cover the complete surface. However many flow configurations which include a significant region of separated flow will be deemed unsatisfactory and an alternative configuration sought. The immediate aims of low-speed three-dimensional turbulent boundary layer research are thus taken to be the prediction of separation, skin friction and effective displacement thickness by a calculation method capable of predicting the boundary layer development up to and including separation.

The work reported here is concerned solely with a turbulent three-dimensional boundary layer and the problems of the initial laminar and subsequent transitional flows are not considered.

As with turbulent two-dimensional boundary-layers no theoretical solution to the development of turbulent three-dimensional boundary layers can be expected in the foreseeable future. Consequently a mixture of theory and empiricism will have to suffice.

The theoretical contribution is generally obtained from the time averaged forms of the continuity equation and the three-dimensional Navier-Stokes equations. After making suitable assumptions about the magnitude of the various terms in the three Navier-Stokes equations, two equations ${ }^{1}$ are obtained which are applicable to the three-dimensional boundary layer flow over a plane surface. These are normally referred to as the boundary-layer equations though there are boundary-layer configurations to which they do not apply such as when the surface has significant curvature, when the flow is along a corner and quite possibly in the vicinity of separation from a plane surface.

The boundary layer equations cannot be solved analytically on account of the turbulent shear stress terms. The general method of obtaining a solution with the assistance of empirical results is to integrate a form of these equations over the total boundary-layer thickness and so produce equations which are less dependent upon the shear stress. The simplest forms of such equations are the momentum equations which only involve the value of the shear stress at the wall. The so called energy equations, derived in the same way, require more detailed information about the shear stress distribution across the boundary layer. A result of these integrations is to increase the number of dependent variables so that the equations can only be solved if sufficient auxiliary equations are formed. It is the choice of these auxiliary equations which characterise most of the calculation methods published ${ }^{2}$ for two-dimensional boundary layers*. To extend these methods to three dimensions further equations have to be introduced and an improved understanding of three-dimensional flows is needed if these equations are to be reliable.

Previous low speed experimental work on three-dimensional turbulent boundary layers (reviewed in Ref. 4) has consisted of making measurements of selected profiles. Such measurements can provide useful information about the nature of three-dimensional profiles and, if accompanied by measurements of skin friction, may lead to a relationship between this important quantity and the characteristics of the profiles corresponding to the two-dimensional logarithmic-law. Such measurements cannot however give information about the development of the boundary layer. The terms of the momentum equations cannot be determined as these contain gradients of the profile integrals. If these terms could be measured, the relative importance of each term could be determined for a particular flow and the effectiveness of proposed auxiliary equations could be tested by using them in the momentum equations in place of some of the measured values and comparing the resultant computed development with the measured development. This is essentially the same procedure that is used to test two-dimensional calculation methods.

[^1]Also it may be possible to deduce the shear-stress distribution from the momentum equations by, in effect, evaluating all the remaining terms in the equations experimentally. To obtain the required experimental data it is necessary to measure profiles and related information over an area of the surface. The selection of which profiles should be measured is somewhat arbitrary. Hall ${ }^{5}$, working in a supersonic nozzle, followed free stream streamlines. This has the advantage that the integrated boundary-layer equations are normally written in streamline co-ordinates but requires the streamlines to be first measured and computed, and unless sufficient streamlines are followed the information obtained along the orthogonals is inadequate. An alternative is to measure the profiles on an arbitrary rectangular grid and to calculate the information along streamlines and their orthogonals subsequently by interpolation. However the equations are probably much easier to use in conjunction with experimental data if they are written in rectangular co-ordinates rather than curvilinear co-ordinates as the difficult curvature and axes-stretching quantities arising in the latter are avoided. The quantity of measurements that must be made is likely to be the same in both cases. In the work reported here a square grid of points was used.

The flow studied was formed by placing an obstruction in a thick two-dimensional boundary layer. The strong pressure gradients imposed by the obstruction, which is photographed in Fig. 1, caused the boundary layer to become three-dimensional and to separate. The flow is characterised by the rapid transformation of an essentially two-dimensional boundary layer into a three-dimensional layer by strong pressure gradients. Considerations of the magnitudes of the terms in the Navier Stokes equations, when applied to this type of flow, shows that in the outer region of the boundary layer the shear-stress terms become small compared with the inertial terms and the normal stress and normal pressure gradient terms are second order throughout the layer. Consequently the boundary-layer equations can be applied to this flow, except possibly very close to separation, although in the momentum integral equations the wall shear-stress terms will be small. Throughout the inner region of the flow the shear-stress terms are of first order showing that although this flow is dominated by the pressure gradient it does retain the essential characteristics of a viscous boundary layer. In interpreting the data presented and in using them to test calculation methods care should be exercised and account should be taken of the characteristics of the flow which are representative of three-dimensional boundary layers in strong pressure gradients.

The experiment was conducted in two parts and the regions of the flow examined in each part are shown in Fig. 2. The measurements were made in the three-dimensional boundary layer upstream of and including the three-dimensional separation at a constant freestream reference velocity of $200 \mathrm{ft} / \mathrm{s}$ throughout. As the data was primarily intended for use with integral calculation methods the time-mean velocity measurements were made using a three tube yaw probe which was chosen in preference to a hot wire arrangement because the former is more robust and easier to use and turbulence measurements were not required.

This Report is essentially a data report giving in full the data obtained and a description of the experimental details. An analysis of the profiles is also included and a comparison with existing profile representations made. The first part of the experiment, which is reported here, was made in the $13 \mathrm{ft} \times 9 \mathrm{ft}$ low speed tunnel at R.A.E. Bedford during October to December 1966.

## 2. Experimental Arrangement.

### 2.1. General Description.

A photograph of the flow obstruction, the floor surface and those parts of the traverse gear which were exposed to the airflow is reproduced in Fig. 1. The leading part of the obstruction was semi-circular (Fig. 3). The diameter was made as large as whas thought possible without causing the resulting threedimensional flow to be signifcantly affected by the tunnel fillets. The downstream part of the obstruction was a simple streamlined shape intended to inhibit additional flow separation and keep the flow as steady as possible. Oil flow on the surface of the obstruction showed that the flow was attached along its length.

The obstruction was mounted directly on to the tunnel floor and the bulk of the traverse gear was housed within it. The traverse gear could consequently be of massive construction, which is desirable for obtaining good positional accuracy, and only a single arm (Fig. 1) extended into the flow. A smooth false floor (Fig. 4) was laid over the tunnel floor which provided a uniform surface for the boundary layer to develop on. This arrangement also enabled the surface to be instrumented.

### 2.2. Obstruction and Traverse Gear.

The leading section of the obstruction was made of fibre-glass and the remainder of ply-wood. The dimensions are shown in Fig. 3. Part of the forward section of the obstruction was cut away to permit the traversing arm to move through an angle of approximately $105^{\circ}$ in the horizontal plane and through a vertical displacement of about $7 \frac{1}{4}$ in. A cylinder was mounted on the traverse gear which moved with the arm and sealed this opening at all times; a part of the cylinder is visible in Fig. 1. With the exception of the arm itself the shape of the flow obstruction was the same for all arm positions though the cut-out made the configuration slightly assymmetric about the centreline.

The traverse gear had four movements, each driven by a remotely controlled motor. Positions in the horizontal plane were obtained by rotating the arm $(\theta)$ and by moving the probe carriage along the arm $(r)$. The arm could also be moved vertically to obtain the required displacement of the probe from the floor (y). Finally the probe was rotated about its tip by a mechanism mounted on the probe carriage $(\phi)$. The range, resolution and accuracy of these movements will be discussed in Section 3.2. The position of each movement was obtained from the output of a commutator transmitter and was displayed on a counter as well as being recorded on an electronic counter for read-out. The system used to control the traverse gear and obtain the data is shown schematically in Fig. 5. The control of the vertical and probe rotational movements were supplemented by feed-back loops. In the case of the vertical movement this was provided by an electronic relay connected between the traverse gear and the aluminium plate that formed the floor. When the probe touched the plate the relay stopped the vertical drive motor which, being fitted with a magnetic brake, stopped the probe in less than 0.010 in . This arrangement protected the probe against damage and the electronic relay could then be used to zero the vertical movement (see Section 3.2). A feed-back on the probe rotating mechanism was provided when the three-tube yaw-probe was fitted. The pressure difference between the two side tubes of the yaw probe was measured on a differential pressure transducer and the output fed into a potentiometric controller. If the out of balance signal exceeded a certain set value the controller operated the probe rotating motor so as to reduce the error. This constituted a simple nulling system which was useful in keeping the probe roughly aligned with the flow at all times. In this way the pressure difference applied to the transducer was kept small so the effects of hysteresis on the zero reading could be kept small. When taking measurements the probe was operated by hand and the transducer was used to determine the null position. The transducer used had a range of $\pm 8$ in of water and was of variable inductance construction.

### 2.3. False Floor.

The obstruction was positioned on the tunnel centreline and surrounded by a smooth false floor (see Fig. 4). The false floor was 1.6 in thick and 21 ft 10 in long extending 13 ft 10 in forward of the model. The leading and trailing edges were tapered down to the tunnel floor and oil flow showed that the flow over the leading edge ramp was attached. The false floor was made of ply-wood panels except for a $4 \mathrm{ft} \times 3 \mathrm{ft}$ panel in the area where the measurements were made which was made of aluminium. The aluminium panel contained 220 magnets of 0.4 in diameter each containing a static hole of 0.030 in diameter. The static holes were arranged on a 2 in $\times 2$ in grid and covered an area slightly larger than that covered by the traverse gear. The magnets and static tappings were used to measure the local skin friction stress by the Preston tube ${ }^{6}$ and razor blade ${ }^{7}$ techniques.

### 2.4. Probes.

Three types of interchangeable probes were used on the traverse gear. The yaw probe (Fig. 6) comprised a three tube yaw head constructed of tubes of $0.020 \mathrm{in} \mathrm{o} / \mathrm{d}$ with a static probe of $0.060 \mathrm{in} \mathrm{o} / \mathrm{d}$ positioned 5 in from it. The method of using the probe is explained in Section 4.2. For the static pressure profile a probe consisting of a single $0.080 \mathrm{in} o / d$ static head was used. The Preston tube measurements were obtained from a probe carrying a single square-cut pitot-head of $0.080 \mathrm{in} \mathrm{o} / \mathrm{d}$.

### 2.5. Pressure Measurements.

The pressure measurements were made with two specially constructed transducers. The transducers consisted of a single bellows which exerted an axial force proportional to the pressure difference across its surface. The force was measured by a strain-gauged arm. The advantage of these transducers was that they could be used with existing standard R.A.E. strain-gauge equipment to provide a digital read-out. The transducers had a range of about $\pm 40 \mathrm{in}$ of water and the calibrated accuracy was found to be determined entirely by the auxiliary electronic equipment. The auxiliary equipment had a full scale read-out of 1000 units and the sensitivity could be adjusted to cover any required pressure range.

### 2.6. Data Recording.

The data was recorded using the tunnel's standard read-out apparatus. The recording took the form of punched cards for subsequent analysis and a type-written copy for immediate use. Seven quantities were recorded comprising a data point number, the four positions of the probe and the two pressure transducer readings.

## 3. Experimental Accuracy and Setting-up Procedures.

### 3.1. Introduction.

As this is essentially a data report, the likely accuracy of the experimental results and possible sources of additional unmeasured errors are now considered. An overall determination of the accuracy of the results can only be obtained from an analysis of the data itself. The scatter of the individual quantities and the balance of the momentum integral equations will probably give the best indication of the extent to which the data may be trusted and the point to which refinement of analysis may reasonably be taken.

An estimate of the accuracy of the component parts of the experimental arrangement can be obtained from calibrations but aerodynamic effects such as arise from traverse gear interference or flow unsteadiness are more difficult to estimate. As the way in which the apparatus is used also effects the accuracy of the results, the setting-up procedures and checks used will be discussed in conjunction with the topic of accuracy.

### 3.2. Probe Position.

The estimated accuracy of the four movements of the traverse gear are tabulated below. The likely standard deviation $(\sigma)$ of the error is listed so that 60 per cent of all measurements should be within $\pm \sigma$ and virtually all within $\pm 3 \sigma$.

| Quantity | Range | Resolution | Setting up $\sigma$ | Measurement $\sigma$ |
| :---: | :--- | :--- | :--- | :--- |
| $r$ | 14 in to $30 \cdot 8 \mathrm{in}$ | 0.01 in | 0.005 in | 0.01 in |
| $\theta$ | $-10^{\circ}$ to $95^{\circ}$ | $0.01^{\circ}$ | $0.01^{\circ}$ | $0.02^{\circ}$ |
| $y$ | 0 to 7.25 in | 0.001 in | 0.001 in | $y<1 \mathrm{in}, 0.001 \mathrm{in}$ |
|  |  |  |  | $y>1 \mathrm{in}, 0.001 y$ |
| $\phi$ | $\pm 180^{\circ}$ | $0.01^{\circ}$ | $0.02^{\circ}$ | $q=q_{0}, 0.03^{\circ}$ |
|  |  |  |  | $q=0.1 q_{0}, 0.10^{\circ}$ |

The quantities $r$ and $\theta$ were set up relative to the aluminium plate with zero tunnel flow and the figures given do not contain any estimate of the wind effect. The deflexion of the traverse gear and of the probe is small but the $\theta$ movement did have significant back-lash. This was partly overcome by a constant tension spring but in use the arm was always rotated onto a given position from the same direction so
that it was driven against the back-lash spring and, in general, the wind forces. The $y$ movement was zeroed using the electronic relay. which proved very satisfactory. This was done for every profile with the wind on and a high accuracy can be expected for small values of $y$. The probe angle, $\phi$, was set up aerodynamically. An arbitrary point in the flow was selected as having zero flow angle and was used as a datum. The point selected was $r=30.00 \mathrm{in}, \theta=0, y=7.000 \mathrm{in}$. The calibration of $\phi$ showed a maximum non-linearity of $0.6^{\circ}$ and back-lash of $0.35^{\circ}$. Consequently in use the probe was always aligned from the same direction and a calibration correction has been used in the computer programme which calculated the results given in this Report. With this procedure the calibrated error of the probe rotating mechanism is about $0.03^{\circ}$. An additional error will arise if the zero of the transducer used to balance the yaw probe is not repeatable. Frequent checks of the transducer suggest that in use its zero repeatability was equivalent to about $0.01^{\circ}$ with the probe in a flow having the reference kinetic pressure $q_{0}$. This error is small compared with the mechanical error of $0.03^{\circ}$, since the combined error is equal to the square root of the sum of the squares of the individual errors, but if the probe is in a flow of $0.1 q_{0}$ then the transducer error, equivalent to $0 \cdot 1^{\circ}$, will predominate. Larger errors than these may occur in some areas due to flow unsteadiness.

### 3.3. Probe Calibration and Pressure Measurement.

The probes used were calibrated in the free stream of the empty tunnel. The static probe of the combined yaw and static probe was of non-standard proportions so as to minimise the effect of the thick stem downstream of it. The geometry of the probe needed to give a small correction was obtained experimentally and calibration showed that a correction of $-0.0145 q$ was required. The other probes required no correction.

The transducers used to measure the tunnel reference pressure and the probe pressure have been described in Section 2.5. Calibration of the transducers and their associated electronics showed that the accuracy was determined by the electronics and was equal to about 0.1 per cent of the full scale pressure which depended upon the sensitivity setting of the electronics. The sensitivity was selected so that the full scale corresponded to the local free stream kinetic pressure, $q$, and so the pressures recorded have an error $\sigma$ of $0.001 q$. A frequent check calibration procedure was used whereby the transducers were arranged to measure $P_{s}-P_{w}=232.0 \mathrm{~mm}$ of water and $P_{w}-P_{w}=0$ and the outputs corresponding to these two values were recorded and used in the computer programme. During the calibration readings the tunnel kinetic pressure was held accurately at 232.0 mm of water as measured by a Betz water manometer, but at other times the pressure was allowed to drift a little. The values obtained of the ratio of the local velocity to the local free stream velocity, $\mathbf{u} / U$, will have an error $\sigma$ of about 0.0005 . This error will be substantially increased in some areas of the flow because of unsteadiness. Also, in regions of very low velocity, particularly when accompanied by significant static pressure gradients in the $y$ direction, the value of $\mathbf{u} / U$ will be much less accurate.

## 4, Experimental Procedure.

### 4.1. Introduction.

The main problem in an experiment of this type is in maintaining a constant standard of work throughout a long period of tunnel running. The apparatus described in Section 2 was designed with this in mind. Nevertheless, the average time taken to produce one complete traverse was about one hour and the total time taken to produce the data given in this Report was 230 hours. The main features of the experiment are now described but many preliminary and check observations that were made will not be specifically described but may be referred to in passing.

### 4.2. Velocity Profiles.

The principal part of the experiment was obtaining the velocity profiles. In the interests of establishing a routine and of easing subsequent computation all the profiles were obtained in exactly the same way. The positions of the profiles were decided in advance and were arranged on a one inch grid as shown in Fig. 7. The distances from the floor surface to the profile points $(y)$ were also decided in advance. Over the
inner part of the boundary layer the values of $y$ were chosen to be a geometric series since, in general, the flow characteristics tend to be well conditioned functions of $\log y$. The actual values used are given by

$$
y=0.010(2)^{n / 2} \text { in , }
$$

for $0.010 \leqq y \leqq 1.280$ where $n$ is an integer. This series of ordinates has the additional advantage that integrals with respect to $y$ are easily computed since

$$
\int f(y) d y=\int y f(y) d(\log y)
$$

and the series gives equal steps of $\log y$. Over the outer part of the boundary layer equal steps of half an inch were taken between $1 \cdot 5$ in and $7 \cdot 0$ in so as to give sufficient detail.

At the start of each profile an overall calibration of the transducers was recorded as described in Section 3.3. The yaw probe was zeroed onto the aluminium plate, using the electronic relay and the read-out was set to a value of half the probe height* ( 0.010 in ). The probe was rotated until a null on the yaw balancing transducer was obtained and a set of data recorded (see Section 2.6). The two pressures recorded were the probe pressure relative to $P_{w}$ and the tunnel reference pressure $P_{s}-P_{w}$. Having repeated the procedure for all the values of $y$ up to 7.000 in the potentiometer controller was switched off and the probe lowered to the $y=3 \cdot 000 \mathrm{in}$ position. This brought the separate static probe to $y=7.000$ in correctly aligned in yaw with the flow and enabled a measure of the static pressure to be obtained with which to calculate the velocity profiles (see Section 5). The pressure leads were then switched and the static pressure recorded on a card. Finally the transducers were calibrated again as at the beginning of the profile. After every second profile the probe was moved to the reference point ( $r=30 \mathrm{in}, \theta=0, y=7 \mathrm{in}$ ) and the zero of $\phi$ was checked and reset if necessary. If an adjustment of more than about $0.05^{\circ}$ was required the tunnel was stopped and the zero of the balancing transducer was checked, otherwise this check was normally made every four profiles. 123 profiles were measured and these were followed by 10 repeat profiles. These repeat profiles were made when the original profile was thought to be in error and were not therefore a check on the normal repeatability of the technique. Doubt about a profile arose either as the result of the tunnel unsteadiness caused by the atmospheric wind or from irregularities in the plot of free stream angle ( $y=7.000 \mathrm{in}$ ) and surface flow angle ( $y=0.010 \mathrm{in}$ ) which were made during the experiment. In the data presented in the next Section seven of the repeat profiles are given in place of the originals. As an additional check the values of free stream angle ( $y=7.000 \mathrm{in}$ ) were surveyed successively over the whole area.

### 4.3. Extended Velocity Profiles.

It is frequently assumed that the free stream outside a three-dimensional boundary layer on a flat plate is such that the conditions of the flow along traverses taken normal to the flat surface are constant. This is a convenient and, no doubt, reasonable assumption, but in practice it is not, and cannot be, strictly accurate. An immediate difficulty that arises from the variation of conditions in the free stream is that of defining the free stream direction and this will be discussed further in Section 5. To obtain a measure of the extent of the three-dimensionality of the free stream, profiles were extended up to $11 \cdot 5 \mathrm{in}$. This was done on a 2 in $\times 2$ in grid using 31 profiles. Only the yaw angle and total head were measured and this was achieved by sliding the probe up about $4 \frac{1}{2}$ inches in its holder so as to extend the effective range of the traverse gear.

[^2]
### 4.4. Static Profiles.

The normal assumptions made in deriving the boundary layer equations yield the result that the static pressure through the boundary layer is constant*. This approximation is generally valid in threedimensional boundary layer flow but cannot be taken for granted particularly in the vicinity of separation. To obtain direct information about the validity of this approximation in the present flow static profiles were measured. This was done on the same $2 \mathrm{in} \times 2$ in grid as was used for the extended profiles (Section 4.3). A separate 0.080 in diameter static probe was traversed through the boundary layer and was positioned so that its static holes were centred on the axis of the traverse. The probe was aligned with the flow in yaw by setting it to the angle obtained from the velocity profiles corresponding to the position of its geometric centre. The probe could not be aligned with the flow in pitch but, as the maximum pitch angle of the unseparated part of the flow will be of order one degree, errors due to this misalignment should be very small.

### 4.5. Preston Tube and Razor Blade Measurements.

Various methods are available for measuring the skin friction but none has the clear advantage of definitely yielding the correct results. The direct measuring floating element method has the disadvantage of being affected by the pressure gradients by an amount that cannot be estimated accurately. It also measures the vector average over a comparatively large area which must reduce its accuracy. Even so, it would be worth using if the necessary equipment and instrumentation were available. The necessary equipment was not available and the task of surveying an area of the surface in this way was considered too formidable to attempt at present. Of the indirect methods Preston tubes, razor blades and hot films are all possibilities. As the necessary apparatus for using hot films was not available the use of both Preston tubes ${ }^{6}$ and razor blades ${ }^{7}$ was thought adequate. A further method of obtaining the skin friction is due to Clauser ${ }^{9}$ and involves plotting the velocity profiles on particular log-linear axes. This method is very useful in two-dimensional flows and its extension to three-dimensional flows is discussed in Section 6.2.
Preston tube and razor blade measurements were made on the same $2 \mathrm{in} \times 2 \mathrm{in}$ grid as used for the extended profiles (Section 4.3) with one additional row of points. At these grid points static pressure tappings and flush mounted magnets had been set in the aluminium ground plate. A 0.080 in diameter Preston tube was attached to the traverse gear and set on the surface at the angle previously obtained from the velocity profiles at $y=0.010 \mathrm{in}$. The same pressure transducer and read-out was used as for the velocity profiles. The razor blades, which were only 0.0050 in high were set to the same surface flow angle by hand. Because the boundary layer was so thick the skin friction was low and the pressure differences recorded by the razor blades were very small (typically $0.02 q_{0}$ ). As this small pressure difference was obtained from two measurements of pressure, made at different times, one with the blade in position and other with it removed, a single Betz manometer was used to improve accuracy. Even so this method makes extreme demands on the repeatability of tunnel conditions and so the results from the razor blades may be significantly less repeatable than those from the Preston tube.

## 5. Experimental Results.

The experimental data are given in Tables 1 to 5 and are deduced directly from the measurements with no smoothing applied. In Table 1 the displacement and momentum integrals are given together with the free stream direction and static pressure. The two measured values of skin friction are listed in Table 2 and the detailed velocity profiles are given in Table 3. Throughout this Report the individual profiles are
*According to Rotta ${ }^{8}$

$$
C_{p}+2\left(\frac{\bar{v}^{2}}{U^{2}}\right)=\text { constant } .
$$

On the surface $\bar{v}^{2} / U^{2}$ is zero and is negligible in the free stream. A typical maximum value of $\sqrt{\bar{v}^{2}} / U$ is 0.05 so that $C_{p}$ may be expected to be reduced by about 0.005 within the boundary layer.
referred to by a number obtained by combining the $Z$ and $X$ co-ordinates. Thus the profile at $Z=6 \mathrm{in}$, $X=24$ in is number 624 , that at $Z=-2 \mathrm{in}, X=30 \mathrm{in}$ is -230 and at $Z=0, X=22 \mathrm{in}$ is 22 . For clarity the profile co-ordinates are listed in Table 3 together with the profile numbers. In Table 3 the velocity is the apparent velocity obtained by assuming that the static pressure through the boundary layer is constant and equal to the values measured at $y=7.000$ in which is given in Table 1 . For a few profiles, close to the saddle separation point, the measured total head was less than the free stream static pressure and in these cases the velocity has been printed as zero. This results from static gradients normal to the surface and very low velocities, and, in the case of profile 21, from reversed flow. As the integrals in Table 1 were obtained using the values given in Table 3, the data for these few profiles may be in significant error. The data obtained from the measurements of static pressure across the boundary layer are listed in Table 4 and in general the static gradients are small. The values of pressure coefficient given for $y=0$ were obtained from the surface static tapping and are in quite close agreement with the probe data. The difference increases to about 0.01 near separation and is probably due to differing effects of turbulence on the static tapping and static probe and to the gradient in the $y$ direction of flow direction which will cause the static probe to register a low pressure. There is a fairly constant difference of about 0.005 between the values obtained at $y=7.000 \mathrm{in}$ from the separate static probe and from combined yaw and static probe. This is probably due to traverse gear interference though differing characteristics of the static probes in curved flows may also contribute. The effect of this possible error on the velocity profiles will be small and should not exceed 0.015 for the lowest values of $u / U$ and will be negligible over most of the boundary layer. The cross flow angles measured on the extended profiles are given in Table 5 and in all cases the total pressure was constant and equal to the tunnel total pressure.

In two-dimensional boundary layers the edge of the boundary layer is normally defined experimentally by

$$
y=\delta \quad \text { at } \quad u / U=0.995
$$

The same definition has been used in presenting the data and the free stream flow direction $(\alpha)$ has been taken as the flow direction at $y=\delta$, though the three-dimensionality of the free stream makes this definition rather arbitrary. In addition $\alpha$ was measured relative to the flow direction at $X=30.00 \mathrm{in}, y=7.000 \mathrm{in}$ and $Z=0$ which is also arbitrary. A set of values of $\alpha$ which have been smoothed and corrected are given in Table 6. The values of $\alpha$ given in Table 1 were first smoothed by an iterative two-dimensional process. The true undisturbed flow direction was then estimated by assuming that it occurs at the upstream end of the data where the transverse velocity integral $\left(\delta_{2}\right)$ is zero. This is shown in Fig. 8 to occur at $Z=0.4$ in. A plot of this corrected value of $\alpha,\left(\alpha^{*}\right)$, against $Z$ is shown in Fig. 9. It is suggested that the point $X=30 \cdot 00$, $Z=0.40$ in would be a suitable origin for a free stream streamline co-ordinate system.

Also shown in Fig. 9 are curves obtained from the two-dimensional potential flow around a cylinder with the same section as the obstruction. The flow field was obtained by representing the body by a distribution of source elements and the strength of these elements was determined by satisfying the solid boundary condition ${ }^{10}$. The tunnel walls were represented by computing the flow through an infinite cascade of bodies. The computation was made both for an infinite flow and for tunnel walls at 13 ft spacing. The latter case is shown in Fig. 9 though the difference between the two calculated results is much less than between the calculated results and the experimental results shown in Fig. 9. These differences are attributed to the three-dimensionality of the free stream arising from the tunnel fillets, which at floor level are only 9ft 9 in apart, the limited height of the obstruction, which did not span the tunnel, and the variations of the floor displacement thickness. The points obtained at $y=11.5 \mathrm{in}$ (Fig. 9) are seen to be slightly closer to the potential solution near the axes of symmetry $(|Z| \simeq 2 \mathrm{in})$. Further information on the comparison between the computed and measured free stream will be given in Part 2.

The region of the flow investigated in this Report is illustrated in Fig. 7 together with the positions of each profile. Using the measured flow directions free-hand streamlines have been drawn which give approximately the surface flow and free-stream streamline patterns. The surface flow pattern is in close visual agreement with the oil flow pattern in Fig. 10. The area of the test will be seen to include the axis
of symmetry of the flow and also the three-dimensional separation line.

## 6. Profile Analysis.

### 6.1. Polar Plot.

The polar plot of the velocity vector is a useful representation of the three-dimensional profile. The importance of this plot is that on it many profiles have been found to take the form of a triangle ${ }^{11}$ (Fig. 11). The cross flow can then be represented by the equations

$$
\begin{equation*}
\frac{w}{U}=\frac{u}{U} \tan \beta_{0} \tag{1}
\end{equation*}
$$

in Region I and,

$$
\begin{equation*}
\frac{w}{U}=A\left(1-\frac{u}{U}\right) \tag{2}
\end{equation*}
$$

in Region II. In relation to the $y$ co-ordinate this plot entails a large distortion since about 99 per cent of the boundary layer thickness can be in Region II. For the purposes of relating the momentum integrals it may be sufficient to assume that Region II extends over the whole boundary layer, then
and

$$
\begin{equation*}
\theta_{12}=A(H-1) \theta_{11}, \quad \theta_{21}=-A \theta_{11}, \quad \theta_{22}=-A^{2}(H-1) \theta_{11} \tag{3}
\end{equation*}
$$

where

$$
\delta_{2}=-A H \theta_{11}
$$

$$
H=\delta_{1} / \theta_{11}
$$

Agreement with this simple model has been found in several flows ${ }^{11,12}$ in which the lateral pressure gradient is monotonic. The present pressure field is of the type and the data fit this representation well. A selection of profiles is shown in Fig. 12.

It has been shown ${ }^{11}$ by inviscid theory that if the free stream is two-dimensional

$$
\begin{equation*}
\operatorname{Lt}_{u \rightarrow U}(A)=2 U^{2} \int_{0}^{\alpha} U^{-2} d \alpha \tag{4}
\end{equation*}
$$

and if the streamwise pressure gradient is zero

$$
\begin{equation*}
\underset{u \rightarrow U}{\operatorname{Lt}}(A)=2 \alpha \tag{5}
\end{equation*}
$$

A minus sign has been omitted from both equations (4) and (5) because the sign of $\alpha$ given in this Report has been defined so as to be positive when $Z$ is positive. This is opposite to the sign convention used in the theory of Ref. 11.

These relationships only apply in the limit and the polar plot in Region II should in general be curved. The empirical observation that in many cases the whole Region II approximates to a straight line on the polar plot suggests that equations (4) and (5) may be used in equation (2). Lines corresponding to $A=2 \alpha^{*}$ are shown in Fig. 12 and are in good agreement with the data particularly as $u / U$ approaches unity.

If the relationships in (3) are accepted then a variety of additional methods of determining $A$ from the data is available. The simplest form appears to be $A=-\delta_{2} / \delta_{1}$ and in Fig. 13 this function is plotted against $\alpha^{*}$ for all the data except the profiles on $Z=0$. There is clearly a strong correlation between the functions though, as expected from the polar plots, in general $-\delta_{2} / \delta_{1}>2 \alpha^{*}$. Using equation (4) in place of equation (5) would make the correlation worse. The three-dimensionality of the free stream could contribute to this discrepancy particularly near the axis of symmetry.

Johnston used the triangular model to relate the surface flow direction ( $\beta_{0}$ ) to $A$ and the component of skin friction in the local free stream direction $\left(C_{f x}\right)$. To do this he assumed that Region I corresponded to the laminar sub-layer so that $\mathbf{u} / U=y u_{\tau} / v$. By assuming in addition that the apex of the triangle corresponds to a particular value of $y u_{\tau} / v$ he obtained the relationship

$$
\begin{equation*}
\frac{\tan \beta_{0}}{A}=0 \cdot 1\left[\frac{\left(1+\tan ^{2} \beta_{0}\right)^{\frac{1}{4}}}{\sqrt{C_{f x}}}\right]-1 \tag{6}
\end{equation*}
$$

The assumption that the apex of the triangle corresponds to a constant value of $y u_{\tau} / v$ has been disputed ${ }^{12}$. In practice it is difficult to measure the correct value of $y u_{\tau} / v$ since it is first necessary to determine the position of the apex of the polar plot and then to infer by some criterion the corresponding value of $y u_{\tau} / v$. Considering that successive points of Fig. 12 represent 41 per cent increases of $y u_{\tau} / v$ this is a very inaccurate process. If however the triangular form of the polar plot is accepted it is sufficient to postulate that the apex is given by

$$
\begin{equation*}
(\mathbf{u} / U)_{\text {apex }}=K u_{\tau} / U \tag{7}
\end{equation*}
$$

where $K$ is the same constant as Johnston ${ }^{11}$ used. By applying the sine rule to the triangular model in Fig. 11,

$$
\sin \left(\beta_{0}+\gamma\right)=\left(K u_{\tau} / U\right)^{-1} \sin \gamma
$$

hence

$$
\begin{equation*}
\beta_{0}=\sin ^{-1}\left\{\left(K u_{\tau} / U\right)^{-1} \sin \gamma\right\}-\gamma \tag{8}
\end{equation*}
$$

Equations (6) and (8) are congruent. The experimental data are compared with equation (8) in Fig. 14 using $\gamma=\tan ^{-1} 2 \alpha^{*}$ and $u_{\tau} / U$ given by the Preston tube. Putting $\gamma=\tan ^{-1} 2 \alpha^{*}$ will in general imply a different fit of the triangular model to the data from that obtained graphically, as shown in Fig. 12. Promising agreement is obtained with a value of $K$ of 14 but the scatter includes a definite trend. This is particularly so when additional data to be given in Part 2 are added. However this trend can be reduced by nondimensionalising $u_{\tau}$ with regard to $U_{0}$ rather than $U$. Equation (8) then becomes

$$
\begin{equation*}
\beta_{0}=\sin ^{-1}\left\{\left(K u_{\tau} / U_{0}\right)^{-1} \sin \gamma\right\}-\gamma, \tag{9}
\end{equation*}
$$

which is no longer related to the triangular model on the polar plot. The data are compared with equation (9) in Fig. 15. A value of $K$ of 17.5 is used and the experimental values of $\beta_{0}$ are linear extrapolations through $y=0.014$ in and $y=0.028 \mathrm{in}$. The agreement is considered satisfactory for all the data and the systematic trend is reduced. Two profiles ( 620 and 820 ) do not yield real solutions to equation (9), which implies that the measured values of $\alpha^{*}$ and $u_{\tau} / U_{0}$ are such that the polar triangle does not meet up. The limiting form, when $\gamma+\beta_{0}=90^{\circ}$, gives values of $\beta_{0}$ for these profiles of $70^{\circ}$ and $67^{\circ}$ which compare reasonably with the measured values of $74^{\circ}$ and $62^{\circ}$.
$U_{0}$ is a constant for all the data so that the correct method of non-dimensionalising $u_{\tau}$ in equation (9) is now in doubt. Many alternative forms could be written down but further data will be required before the optimum non-dimensional form can be decided. However the agreement obtained in Figs. 14 and 15 suggest that equations (8) and (9) may be useful, particularly in monotonic flows.

### 6.2. Logarithmic Plot.

The plot of $u / u_{\tau}$ against $\log \left(y u_{\tau} / v\right)$ has proved very useful in the analysis of two-dimensional boundary layers in moderate pressure gradients. In the inner 10 per cent or so of the boundary layer this representation of the profile gives a unique curve. For values of $\left(y u_{\tau} / v\right) \geqq 30$ the curve is straight and is given by the equation of the 'logarithmic law', which is

$$
\begin{equation*}
u / u_{\tau}=A \log \left(y u_{\tau} / v\right)+B \tag{10}
\end{equation*}
$$

Clauser ${ }^{9}$ wrote this equation as,

$$
u / U=\left(u_{\tau} / U\right)\left\{A \log (y U / v)+A \log \left(u_{\tau} / U\right)+B\right\}
$$

which enables straight lines of constant $u_{\tau} / U$ to be drawn on a plot of $u / U$ against $\log (y U / v)$. This plot provides a quick way of deducing the value of $u_{\tau} / U$ from a given velocity profile.

Some examples of the present data are shown in Fig. 16 plotted as $\mathbf{u} / U$ against $\log _{10}(y U / v)$. Lines are also shown corresponding to the values of $u_{\tau} / U$ obtained from the Preston tube and razor blades. In Fig. 16 a displacement correction of +0.004 in has been applied to $y$. Profiles 30 and 26 are almost collateral though the adverse pressure gradients are severe. The curves agree at their lower ends with the razor blade lines and a limited logarithmic region is present in Profile 30. The remaining profiles in Fig. 16 are three-dimensional to varying extents. In addition to $\mathbf{u} / U, w / U$ is plotted and also $u / U$, where it differs significantly from $\mathbf{u} / U$. As might be expected there is general agreement between the $\mathbf{u} / U$ profiles and the positions of the straight lines corresponding to the values of $u_{\tau} / U$ obtained from the Preston tube and razor blades. There is, however, a tendency for the profiles to be curved such that in the region of $\log _{10}$ $(y U / v)$ equals 4.0 to 4.5 they drop below the Clauser line which fits the points at $\log _{10}(y U / v)$ equals 3.0 to 3.5. This is particularly clear in Fig. 16 Profile 820 . Joubert and Perry ${ }^{13}$ found the same curved form and proposed an alternative plot. They observed that $s / U$ given by

$$
s / U=U^{-1} \int_{0}^{u}\left(1+\left(\frac{d w}{d u}\right)^{2}\right)^{\frac{1}{2}} d u
$$

produced a more nearly linear region and by extending mixing-length theory to three dimensions deduced the general form that $s / U$ should take. The function $s / U$, which is the length of the curve on the polar plot, is plotted on Fig. 16 and will be seen to be a little closer to the logarithmic law though in Profiles 824 and 820 , in particular, it is continuously curved. Joubert and Perry did not obtain very satisfactory agreement between the experimental form of $s / U$ and the form deduced by mixing-length theory, and a few exploratory calculations on the present data were also unsatisfactory.

Another method that is sometimes adopted is to deduce the skin friction from the $u / U$ profile as if it is two-dimensional and to call the value of the skin-friction velocity obtained $u_{\tau x}$. This method is used because the $u / U$ profile generally exhibits a linear region, as shown in Fig. 16 (e.g. Profile 820 is linear from $\log _{10}(y U / v)$ equals 3.0 to 4.0 ), but it does not follow that the correct value of skin friction is deduced. Johnston ${ }^{14}$ has proposed an improved method of deducing the skin-friction velocity from the observed linear region and this method is now considered in detail.

The law of the wall in two dimensions states that $u / u_{\tau}$ is a unique function of $\left(y u_{\tau} / v\right)$. Thus,

$$
\begin{equation*}
u / u_{\tau}=f\left(y u_{\tau} / v\right) \tag{11}
\end{equation*}
$$

In three dimensions equation (11) may be expected to be true in the limit as $y$ tends to zero. In this limit equation (11) becomes,

$$
\begin{equation*}
\mathbf{u} / u_{\mathrm{r}}=f\left(y u_{\mathrm{r}} / v\right), \tag{12}
\end{equation*}
$$

and also

$$
\mathbf{u}=u \sec \beta_{0}
$$

Hence,

$$
\begin{equation*}
u \sec \beta_{0} / u_{\tau}=f\left(y u_{\tau} / v\right) \quad \text { as } \quad y \rightarrow 0 \tag{13}
\end{equation*}
$$

For any particular profile ( $\sec \beta_{0} / u_{\tau}$ ) is a constant. The left hand side of equation (13), $u \sec \beta_{0} / u_{\tau}$, is therefore proportional to $u / U$ which, as mentioned above, has been found experimentally to exhibit a logarithmic region. It is proposed, therefore, that equation (13) be applied throughout the normal law of the wall region. In the logarithmic region equation (13) then becomes

$$
\begin{equation*}
u \sec \beta_{0} / u_{\tau}=A \log \left(y u_{\tau} / v\right)+B \tag{14}
\end{equation*}
$$

where $A$ and $B$ are the log-law constants for two-dimensional boundary layers. To obtain the Clauser plot, equation (14) is written as

$$
\begin{equation*}
u \sec \beta_{0} / U=\left(u_{\tau} / U\right)\left\{A \log (y U / v)+A \log \left(u_{\tau} / U\right)+B\right\} \tag{15}
\end{equation*}
$$

Thus a plot of $\left(u \sec \beta_{0} / U\right)$ against $\log (y U / v)$ should enable the skin-friction velocity $\left(u_{\tau} / U\right)$ to be deduced. This plot is also shown in Fig. 16 wherever $\left(u \sec \beta_{0} / U\right)$ differs significantly from $\mathbf{u} / U$. Linear regions are produced which generally follow log-law lines and the form of the ( $u \sec \beta_{0} / U$ ) profiles are similar to the $u / U$ profiles on the centreline (e.g. Profile 424 is in a strong adverse pressure gradient and the ( $u$ sec $\beta_{0} / U$ ) profile is similar to the centreline Profile 26 which is also in a strong adverse pressure gradient). This similarity suggests that the effects of pressure gradients are significant and that in a more moderate pressure field the ( $u \sec \beta_{0} / U$ ) profiles will have longer log-law regions.

On the present evidence the above method of plotting ( $u \sec \beta_{0} / U$ ) on a conventional two-dimensional Clauser plot appears to give the correct value of $u_{\tau} / U$ providing the pressure gradients are not too severe. This conclusion implies that a direct plot of $u / U$ will give neither $u_{\tau} / U$ nor $u_{\tau x} / U$. However, for small cross
flows, when $\sqrt{\sec \beta_{0}} \simeq 1$, a plot of $u / U$ will be sufficiently accurate to give the value of $u_{\tau x} / U$.
It is tempting at this stage to regard the whole of the $\left(u \sec \beta_{0} / U\right)$ profile as a two-dimensional equivalent of the real three-dimensional profile. If this is done, existing skin-friction laws can be applied to the equivalent profile and the skin-friction obtained. Any skin-friction law can be used providing the actual pressure gradient comes within its range of application. A simple table of equivalent quantities can be drawn up as follows

| Two-dimensional quantity | Equivalent three-dimensional quantity |
| :---: | :---: |
| $\theta$ | $\theta_{11}$ |
| $H$ | $H$ |
| $R_{\theta}$ | $R_{\theta_{1} \sec \beta_{0}}$ |
| $C_{f}$ | $C_{f} \cos ^{2} \beta_{0}$ |

The present data do not provide a good test of this concept because the pressure gradients are such that no known skin-friction law would be applicable even if the flow were two-dimensional. A tentative comparison is shown in Fig. 17. A skin-friction relationship due to Green ${ }^{15}$ has been modified to take account of the severe adverse pressure gradients by making it give approximate agreement with the data along the centreline. This modified relationship has then been applied in the manner suggested above to the three-dimensional data and the results are shown in Fig. 17. The comparison is inevitably inconclusive but it is suggested that this method of extending two-dimensional skin-friction laws to three-dimensional flows may be effective in more moderate flows.

### 6.3. Mager's cross-flow profile.

Mager ${ }^{16}$ proposed that the cross flow could be related to the streamwise profile by the equation

$$
\begin{equation*}
w / u=(1-y / \delta)^{2} \tan \beta_{0} . \tag{16}
\end{equation*}
$$

This equation is a particular form of Prandtl's ${ }^{17}$ more general suggestion that

$$
\begin{equation*}
w / u=g(y / \delta) \tan \beta_{0} \tag{17}
\end{equation*}
$$

and was obtained from the data of Gruschwitz ${ }^{18}$. Mager demonstrated that equation (16) does not represent the data of Burgess ${ }^{19}$ well and Fig. 18 shows that it does not represent the present data. If the bottom 10 per cent of the boundary layer is ignored then equation (16) becomes a tolerable representation and part of the inadequacies of equation (16) can probably be attributed to a lack of reliable data in the inner region in old data. It is possible that another polynomial form of $g(y / \delta)$ in equation (17) may give better overall results but it seems likely that the form of equation (17) is too simple and restrictive to represent quickly changing flows of this type.

### 6.4. Coles's and Thompson's profiles.

The two most successful profile representations in two-dimensional flows are due to Coles ${ }^{20}$ and Sarnecki ${ }^{21}$. Sarnecki's method has been developed further by Thompson ${ }^{22}$. The methods are similar in that they use as a basis the well established logarithmic law and extrapolate it to the edge of the boundary layer. Coles then adds a function of $y / \delta$ of fixed shape and correct magnitude to satisfy the end condition $u=U$ at $y=\delta$ : this function is generally called the wake function. Coles's representation does not satisfy the condition $d u / d y=0$ at $y=\delta$. Sarnecki and Thompson overcame this limitation by compounding the velocity from a proportion of the velocity given by the logarithmic law and the remainder of free stream velocity. The proportions vary through the boundary layer according to a weighting function. This representation satisfies both the end conditions $u=U$ and $d u / d y=0$ at $y=\delta$.
Coles suggested that his representation could be extended to three dimensions by treating the two component parts as vectors and taking the logarithmic-law vector in the direction of the surface shear stress. The magnitude and direction of the wake function is then given by the free stream condition. It follows that the profile of the velocity component normal to the surface shear stress should have the form of the wake function. Hornung and Joubert ${ }^{12}$ have shown that this is not true for their data and Fig. 19 shows that it is also not true for the present data. A similar procedure might be followed for extending Thompson's profiles to three dimensions. The three-dimensional profile could be constructed by taking the vector sum of the logarithmic-law vector and the free stream vector in the proportions given by the weighting function. If this is done the profile of the velocity component normal to the surface shear stress vector will have the form of the weighting function. As the wake function and one minus the weighting function are closely similar both are shown in Fig. 19 by the same curve and so this extension of Thompson's profiles is not confirmed experimentally.
Both Coles's and Thompson's profiles are based upon data obtained in slowly changing two-dimensional boundary layers and it is probable therefore that the proposed extensions to three dimensions would be more successful if they were applied to slowly changing three-dimensional flows than they are shown to be for the present rapidly changing flow.

## 7. Conclusions.

Extensive information is given of a turbulent three-dimensional boundary layer produced by an obstruction placed in a two-dimensional boundary layer flow. The area of the flow studied is directly upstream of the obstruction and extends downstream as far as the boundary layer separation line. The flow is dominated by the large pressure gradients produced by the obstruction and the influence of the shear stress is mainly restricted to the region of the flow close to the surface. Also, in the region of the separation line, the normal boundary layer approximations are invalidated by significant pressure gradients through the layer.
The analysis presented in this Report suggests that the experimental data have been obtained with an acceptable accuracy and the data, which were obtained primarily for improving integral calculation methods, have been compared with several existing theories of two- and three-dimensional boundary layers.

The velocity profiles are shown to be in good agreement with Johnston's triangular model. A relationship between the magnitude and direction of the skin-friction vector and the local free stream conditions is proposed and verified experimentally. This relationship, like the triangular model, is probably valid in flows with monotonic transverse pressure gradients. The use of the logarithmic plot in three dimensions is discussed and methods of deducing the magnitude of the skin-friction vector considered. The effects of pressure gradients on the log-law are shown to be significant both on the axis of symmetry of the flow and elsewhere.

Mager's cross-flow profile is shown not to fit the present data and simple extensions to three dimensions of existing methods of representing two-dimensional profiles, using Coles's wake function and Thompson's weighting function, are also shown not to fit the data. The failure of these methods is attributed, at least in part, to the severity of the pressure gradients present in the flow studied.

## LIST OF SYMBOLS

$C_{f} \quad$ Skin-friction coefficient based on local free stream kinetic pressure
$C_{f x} \quad$ Component of $C_{f}$ in $\mathbf{U}$ direction
$C_{p} \quad$ Static-pressure coefficient
$H \quad H=\delta_{1} / \theta_{11}$
$K \quad$ Constant (see equation (7))
$P_{s} \quad$ Settling chamber reference pressure
$P_{w} \quad$ Working section reference pressure
$q \quad$ Kinetic pressure
$u_{\tau x} \quad$ Component of $u_{\tau}$ parallel to $\mathbf{U}$, equal to $u_{\tau} \cos ^{\frac{1}{2}} \beta_{0}$
$w \quad$ Component of $\mathbf{u}$ normal to $\mathbf{U}$
$X \quad$ Cartesian co-ordinate (see Fig. 3)
$y$ Displacement of probe centre from surface
$Z \quad$ Cartesian co-ordinate (see Fig. 3)
$\alpha \quad$ Angular displacement of free stream
$\beta \quad$ Boundary layer cross flow angle. The angle between $\mathbf{u}$ and $\mathbf{U}$
$\beta_{0} \quad$ Value of $\beta$ in the limit as $y$ tends to zero
$\gamma=\tan ^{-1} A$ (see Fig. 11)
$\delta \quad$ Boundary layer thickness $y=\delta$ at $\mathbf{u} / U=0.995$

## LIST OF SYMBOLS-continued

$\delta_{1} \quad \int_{0}^{\delta}\left(1-\frac{u}{U}\right) d y$
$\delta_{2} \quad-\int_{0}^{\delta} \frac{w}{U} d y$
$\theta \quad$ Traverse gear arm angular position
$\theta_{11} \quad \int_{0}^{\delta}\left(1-\frac{u}{U}\right) \frac{u}{U} d y$
$\theta_{12} \quad \int_{0}^{\delta}\left(1-\frac{u}{U}\right) \frac{w}{U} d y$
$\theta_{21} \quad-\int_{0}^{\delta} \frac{u w}{U^{2}} d y$
$\theta_{22} \quad-\int_{0}^{\delta} \frac{w^{2}}{U^{2}} d y$
$v \quad$ Kinematic viscosity of fluid
$\rho \quad$ Density of fluid
$\tau \quad$ Skin friction
$\phi \quad$ Angular position of probe measured relative to traverse gear arm

## Low-Speed Three-Dimensional Turbulent BoundaryLayer Data Part 2

## Summary.

A comprehensive low speed three-dimensional turbulent boundary layer experiment is described and the results are presented in detail. The flow caused by an obstruction placed in a thick two-dimensional boundary layer is investigated at a free-stream velocity of $200 \mathrm{ft} / \mathrm{sec}$. A typical Reynolds number based on the boundary layer momentum thickness and local free-stream velocity is 50000 .

Profiles obtained upstream of the free-stream inflexion are well represented by Johnston's triangular model. Polar profiles further downstream become more curved and are not well represented by a triangle, though the change from an inner region to an outer region is clear. The method discussed in Part 1 for deducing the skin friction from the three-dimensional profile by using a modified law of the wall is shown to be equally applicable to the present data. Mager's cross-flow profile and simple extensions to three dimensions of existing methods of representing two-dimensional profiles, using Cole's wake function and Thompson's weighting function. are all shown not to fit the data.

This part is concerned with the flow to one side of the obstruction and the main characteristic of this region is that it contains a free-stream inflexion.

## 1. Introduction.

This second part of the Report is written to be read in conjunction with Part 1, where a full description of the experiment is given.

The regions of the flow studied in the two parts of the experiment are illustrated in Fig. 2 of Part 1. In the first part, the decelerating and diverging flow directly upstream of the obstruction was studied. In this part, the flow to one side of the obstruction is investigated and, as shown in Fig. 1, the flow contains a free-stream inflexion. The significance of a free-stream inflexion is that it indicates that the pressure gradient normal to the free-stream streamline changes sign. This change in the transverse pressure gradient can be expected to have a significant effect on the transverse mass flow within the boundary layer and on the detailed shape of the velocity profiles.

The data obtained in the second part of the experiment are presented and an analysis of the characteristics of the profiles is given which is similar to that given in Part 1.

The experimental results given were obtained in the $13 \mathrm{ft} \times 9 \mathrm{ft}$ low-speed tunnel at R.A.E. Bedford in the period October to December, 1967.

## 2. Experimental Details.

The equipment used in the experiment was the same as that described in detail in Part 1, except that the operation of the traverse gear was improved by two minor modifications. The two angular motions of the traverse gear were improved by the replacement and addition of parts so that they maintained their reliability over the larger ranges required for this part of the experiment. The measurement of the angular position of the traverse gear arm was improved by the addition of a Bendix Electronics 1000 step Rotapulse geared directly to the arm. The probe rotating mechanism was improved by replacing a slightly damaged 3000:1 gear box by a new and superior 1000:1 gear box. This change improved the linearity of the mechanism although the resolution was reduced from $0.01^{\circ}$ to $0.03^{\circ}$. An incidental result of this change was that the hysterisis was greatly reduced because the new gear box was reversible which enabled the anti-backlash spring to take up all the hysterisis between the probe and the transmitter.

The experimental procedure was the same as described in Part 1. Eighty-three traverses were made from $y=0$ to $y=7.000$ inches on a 2.0 inch grid at the positions shown in Fig. 1. Six traverses were repeated. A two inch grid was used in place of the one inch grid used in Part 1 partly to enable a much larger area of the flow to be covered but also because the gradients of the flow quantities in the $X$ and $Z$ directions were, in general, less than in the flow immediately upstream of the obstruction (Part 1). At a reduced number of positions the velocity traverses were extended into the freestream up to $y=11.5$ inches and static pressure traverses were made within the boundary layer. Finally, indirect measurements of skin friction were made at all eighty-three positions using a Preston ${ }^{1}$ tube mounted on the traverse gear and at about half the positions using small segments of razor blade attached magnetically to the surface ${ }^{2}$. In Part 1 a Betz water monometer was used in conjunction with the razor blades but because of the very small orifice beneath the sharp edge of the razor blades the response of the manometer was very slow. A considerable saving in time was achieved in the present part by using a Texas fused-quartz precision pressure gauge.

## 3. Experimental Results.

The experimental data are given in Tables 1 to 5 and are deduced directly from the measurements with no smoothing applied. In Table 1 the displacement and momentum integrals are given together with the free-stream direction and static pressure. The two measured values of skin friction are listed in Table 2 and the detailed velocity profiles are given in Table 3. As in Part 1, the profiles are referred to by a number obtained by combining the $Z$ and $X$ co-ordinates. These profile numbers are listed in Table 3 together with the co-ordinates (note profile at $Z=30$ inches, $X=-2$ inches is number 2998 etc.). The values of the static-pressure coefficient obtained from the traverses of the static probe across the boundary layer are listed in Table 4 and in general the static gradients are small. Close to separation a small reduction in pressure occurs which is centred at between 10 and 20 per cent of the boundary layer thickness from the surface. The reduction of pressure, which increases as the separation line is crossed and the separated region entered, is associated with the region of comparatively high suction that occurs within
the separated region and which suggests a large concentration of vorticity ${ }^{3}$.
The extended velocity profiles are given in Table 5 and the data show that the variations of the flow angle in the free-stream is small except near and above the separated region.

The region of the flow investigated is illustrated in Fig. 1 together with the positions of the traverses. Using the measured flow directions free-hand streamlines have been drawn which give approximately the streamline patterns very close to the surface and at the outer edge of the boundary layer. The flow pattern close to the surface is in close visual agreement with the pattern obtained by the oil flow visualisation technique as shown in Fig. 10 of Part 1. The pattern at the outer edge of the boundary layer is compared with the computed potential flow in Section 4. Fig. 1 shows that the free-stream streamlines pass through inflexions and consequently the lateral pressure gradient acting upon the boundary layer changes sign as the flow progresses.

In Fig. 2 the skin-friction field is depicted for the whole region studied in both parts of the experiment. In addition to the free-hand surface streamline pattern, contours of constant skin friction are shown. On the axis of symmetry $(Z=0)$ the skin friction falls to zero at the separation point. Two similar separation lines emanate from the saddle point ${ }^{4}$ and Fig. 2 shows that the magnitude of the skin friction exhibits no peculiarities on crossing the separation line, nor is it zero at any point other than the saddle point. Rather the skin friction on the separation line rises rapidly under the influence of the strong favourable pressure gradient acting in the same direction as the sub-layer flow. Maximum skin friction is reached on the separation line just ahead of the $Z$ axis and thereafter a more gradual fall in skin friction is to be expected under the influence of a moderate adverse pressure gradient. The level of skin friction in the separated region is high and probably reaches a maximum beneath the concentrated vorticity ${ }^{3}$. No measurements are avilable to confirm this but the oil flow (Fig. 10, Part 1) indicates a high level of skin friction throughout the separated region and measurements ${ }^{5,6}$ on the lifting surface of a slender wing showed that there was a large increase in skin friction beneath the leading-edge vortex.

## 4. Freestream.

The two-dimensional flow around a cylinder with the same section as the obstruction is now compared with the measured flow field outside the boundary layer. Data from both Parts 1 and 2 are used.

The potential flow field was obtained by representing the body by a distribution of source elements and the strength of these elements was determined by satisfying the solid boundary condition ${ }^{7}$. The tunnel walls were represented by computing the flow through an infinite cascade of bodies. The computation was made both with an infinite flow and with tunnel walls at 13 ft spacing, but as the difference between the computed results was small, only the solution with the walls represented is used in this Report.

Fig. 3 shows that the measured velocity was less than the calculated value over most of the flow field but was greater than the calculated value near the axis of symmetry directly upstream of the obstruction. Fig. 4a shows that the measured flow angle at the edge of the boundary layer was less than the twodimensional calculated value and that the difference increased to about $4^{\circ}$ as the flow approached and crossed the separation line. Fig. 4 b shows that a broadly similar pattern existed at $y=11.5$ inches (approximately $2 \delta$ ) but that the extent of the maximum difference was reduced to $2.5^{\circ}$.
It is suggested that these differences are caused by the three-dimensionality of the actual flow resulting from the limited height of the obstruction, which did not span the tunnel, and the variation of the displacement thickness of the floor boundary layer. The limited height of the obstruction will result in the flow ahead of it diverging in the $X-y$ plane, that is $\partial v / \partial y$ will be positive, where $v$ is the velocity in the $y$ direction. This is consistent with the measured divergence of the $X-Z$ plane being about 25 per cent less than the two-dimensional potential-flow solution while the measured velocity is only about 2 per cent high. As a result of this vertical divergence ahead of the obstruction the velocity to the side of it will be low (Fig. 3). The changes to the flow field near the floor boundary layer resulting from the limited height of the model can be expected to vary in the $X, y$ and $Z$ directions with a length scale the same order as the height of the obstruction. The rapid increase, in the $X-Z$ plane, of the difference between the measured and calculated values of $\alpha$, shown in Fig. 4a, as the separation line is crossed and the appreciable reduction in the $y$ direction of this difference, shown by comparing Fig. 4a and Fig. 4b, are likely to be due to the displacement effect of the floor boundary layer. The differences are certainly consistent with the induced
flow that would be caused by a vortex extending around the front of the obstruction in the separated region. The oil-flow pattern and the measurements in the separated region ${ }^{3}$ suggest the presence of a vortex-like flow. However, it cannot be stated with certainty that the major effect of the boundary layer displacement distribution is the same as this clearly visible vortex flow and some doubt must remain.

It is concluded that the relatively small differences between the measured free-stream field and the two-dimensional potential-flow solutions are qualitatively consistent with the three-dimensional effects likely to be caused by the limited height of the obstruction and the displacement thickness of the floor boundary layer.

## 5. Profile Analysis.

### 5.1. Polar Plot.

A selection of profiles is shown in Fig. 5. In this figure profiles 1614, 2204 and 2206 are within the separated region as shown in Fig. 1. Considerable deviation from the simple triangular model proposed by Johnston ${ }^{8}$ will be seen. The triangular model was shown to fit the data of Part 1 well but amongst the present data a reasonable fit is only obtained for the most upstream profiles (e.g. profile 1626). Elsewhere the outer region of the boundary layer becomes progressively more curved on the polar plot with distance downstream. Nevertheless two regions are distinguishable and are separated by a clearly defined apex. It can also be seen in Fig. 5 that after the free-stream has passed through its inflexion point and the lateral pressure gradient has changed sign, which occurs at approximately profile 2214 and slightly upstream of profile 2812, the reduction of the transverse velocity ( $w$ ) is greatest in the outermost region of the boundary layer (say $u / U>0.9$ ) and that the corresponding change in the middle region in the vicinity of the apex lags behind. This deduction can be made from Fig. 5 although the sets of profiles shown are at constant $Z$ and not along streamlines. For any particular profile shown in Fig. 5 the profiles on the same free-stream streamline upstream of the inflexion will be in close agreement with the simple triangular model so that the qualitative change that the profile has undergone since the inflexion can be deduced directly from its shape. Even for this complex flow the equation

$$
\begin{equation*}
\underset{u \rightarrow U}{L t}\left(\frac{w}{U-u}\right)=2 \alpha^{*}, \tag{1}
\end{equation*}
$$

where $\alpha^{*}$ is the corrected angular displacement of the free-stream, is quite closely followed. This is shown in Fig. 5 by the agreement, as $u / U \rightarrow 1$, between the data and the lines representing

$$
\begin{equation*}
w / U=2 \alpha^{*}(1-u / U) . \tag{2}
\end{equation*}
$$

The position of the apex is appreciably further out in the boundary layer than in the data of Part 1 and the inner region extends up to $y / \delta \bumpeq 0 \cdot 1$. Also the inner region is not always linear. Upstream profiles such as 1626,1624 and 1622 appear to exhibit a mildly curved inner region such that $\partial^{2} w / \partial u^{2}$ is negative. Further downstream profiles such as 1616,2214 and 2812 have inner regions which are closely linear ( $\partial^{2} w / \partial u^{2} \bumpeq 0$ ) and still further downstream profiles such as 2802,2800 and 2798 appear to be curved such that $\partial^{2} w / \partial u^{2}$ is positive. This behaviour is more closely demonstrated in Fig. 6 in which the cross-flow angle $\beta$ is plotted against the $y$ co-ordinate. In this figure $y$ is corrected for probe displacement effects by +0.004 inch: this correction is the same as applied in Part 1. It will be seen in Fig. 6 that over the innermost region ( $y<0.1 \mathrm{inch}$ ), the slope of the $\beta$ against $y$ curves change in going from profile 2218 to profile 2210. This change of slope is identifiable with the change of sign of the pressure gradient normal to the surface shear stress. It is straightforward to show directly from the boundary layer momentum equations that in the limit as the surface is approached

$$
\begin{equation*}
\underset{y \rightarrow 0}{L t} \partial \beta / \partial y=-\left(2 C_{f_{0}}\right)^{-1}\left(\partial C_{p} / \partial n\right) \tag{3}
\end{equation*}
$$

where $n$ is taken normal to the surface shear stress.
The curves through the experimental points in Fig. 6 have therefore been extrapolated to the wall in such a way that at the wall they have the limiting slope given by equation (3). Provided the points at $y=0.014$ inch are ignored and it is appreciated that equation (3) can at the most be applied throughout the laminar sub-layer which is about 0.002 inch thick, the calculated limiting slopes seem consistent with the data. The data at $y=0.014$ inch were obtained with the probe touching the surface and so are likely to be in error.

Further evidence of the response of the boundary layer as a whole to changes of the transverse pressure gradient is shown in Fig. 7 where $\left(-\delta_{2} / \delta_{1}\right)$ is plotted against $\alpha^{*}$. Points relating to profiles having the same value of $Z$ have the same symbol and points corresponding to constant values of $X$ are connected by dotted lines. These symbols and dotted lines show a clear pattern. Also shown in Fig. 7 are the loci of the free-stream streamlines drawn in Fig. 1 and labelled with the letters A to E, and the locus of the separation line. Also shown is the line $\delta_{2} / \delta_{1}=-2 \alpha^{*}$ which would hold if equation (2) applied to the complete boundary layer. The data in Part 1, which are well represented by the triangular model, also fit this line closely. The present data (Fig. 7) clearly do not fit and, as expected from the shape of the polar plots in Fig. $5,\left(-\delta_{2} / \delta_{1}\right)$ is in many cases much greater than $2 \alpha^{*}$. The upstream ends of the streamlines appear to be tending to $\delta_{2} / \delta_{1}=-2 \alpha^{*}$ which agrees with Part 1 in that the upstream ends of these streamlines are all subjected to a monotonic transverse pressure field and a starting value of $\alpha^{*}$ of zero. However as the inflexion point of the free-stream streamline is approached $\left(-\delta_{2} / \delta_{1}\right)$ rises more rapidly than $2 \alpha^{*}$. $\left(-\delta_{2} / \delta_{1}\right)$ continues to increase as the inflexion point is passed, at which $\alpha^{*}$ reaches its maximum, and throughout an appreciable distance downstream during which $\alpha^{*}$ is falling. Finally after $\left(-\delta_{2} / \delta_{1}\right)$ has reached a maximum it decreases with further reductions of $\alpha^{*}$. Fig. 7 also appears to show that the separation line follows quite closely the locus of the maximum of $\left(-\delta_{2} / \delta_{1}\right)$. This conclusion must be treated with caution since in the immediate vicinity of separation and particularly in the separated region the value of $\left(-\delta_{2} / \delta_{1}\right)$ may be in significant error due to the static pressure gradients through the boundary layer.

Two equations were proposed in Part 1 relating the magnitude and direction of the skin-friction vector to the free-stream conditions. These equations are

$$
\begin{equation*}
\beta_{0}=\sin ^{-1}\left\{\left(K u_{\tau} / U\right)^{-1} \sin \gamma\right\}-\gamma \tag{4}
\end{equation*}
$$

which was derived directly from the triangular model, and

$$
\begin{equation*}
\beta_{0}=\sin ^{-1}\left\{\left(K u_{\tau} / U_{0}\right)^{-1} \sin \gamma_{1}^{\prime}-\hat{\ddots}\right. \tag{5}
\end{equation*}
$$

which was found to give better agreement with the data. $\gamma$ is the included angle between the side of the polar triangle representing the outer region of the boundary layer and the $u / U$ axis (see Fig. 11 of Part 1). For the data in Part 1, equation (2) represented this side of the polar triangle closely so that $\gamma$ could be written as

$$
\begin{equation*}
\gamma=\tan ^{-1} 2 \alpha^{*} \tag{6}
\end{equation*}
$$

Equation (5) with $\gamma$ given by equation (6) is applied to the present data in Fig. 8 and good agreement is not obtained. However a qualitative similarity can be seen between Fig. 7 and Fig. 8, which suggests that $\alpha^{*}$ is not the proper independent variable to use in equation (6). An alternative form, which reduces to equation (6) for the data of Part 1 for which $\delta_{2} / \delta_{1}=-2 \alpha^{*}$, is

$$
\begin{equation*}
\gamma=-\tan ^{-1}\left(\delta_{2} / \delta_{1}\right) \tag{7}
\end{equation*}
$$

The use of equation (7) implies that the side of the polar triangle which represents the outer region of the boundary layer is a weighted mean of the actual profile data. Equation (7) is not related directly to free-stream conditions but rather infers the existence of an equivalent polar triangle for profiles which do
not fit the triangular model closely. Equation (4) with $\gamma$ given by equation (7) is applied to the data in Fig. 9 and equation (5) with $\gamma$ given by equation (7) is used in Fig. 10. These figures include all the data from Parts 1 and 2 for which Preston tube measurements were made with the exception of profiles which are either within the separated region or on the separation line. This last group of profiles have experimental values of $\beta_{0}$ greatly in excess of the calculated values. The values of $K$ used in Figs. 9 and 10 were obtained by writing equations (4) and (7) in the form

$$
\begin{equation*}
U / u_{\tau}=K\left(\cos \beta_{0}-\left(\delta_{1} / \delta_{2}\right) \sin \beta_{0}\right) \tag{8}
\end{equation*}
$$

and equations (5) and (7) in the form

$$
\begin{equation*}
U_{0} / u_{\tau}=K\left(\cos \beta_{0}-\left(\delta_{1} / \delta_{2}\right) \sin \beta_{0}\right) \tag{9}
\end{equation*}
$$

and in each case taking the mean value of $K$ for all the data shown in Figs. 9 and 10. Fig. 9 shows a wide and fairly systematic spread of the data which is very much reduced in Fig. 10. The standard deviation of the individual values of $K$ using equation (9) is 1.07 which is 5.5 per cent of the mean. A slight trend is discernable in the individual values of $K$ throughout the data and can also be seen in Fig. 10. This trend may be a genuine limitation of equation (9) or it may be a systematic error in the value of skin friction deduced from the Preston tube caused by the change from strong adverse pressure gradient to strong favourable pressure gradient in the data. From a consideration of the data it appears that the form of equation (9) is such that it gives a more accurate evaluation of $u_{\tau} / U_{0}$ than of $\beta_{0}$ when compared on a percentage basis.
Equation (9) is of course entirely empirical but its derivation is such that it holds exactly for any profile which, when plotted in a polar plot of $\mathbf{u} / U$, takes the form of a triangle complying with the following two conditions.
(1) The magnitude of the velocity at the apex of the triangle is given by

$$
(\mathbf{u} / U)_{\mathrm{apex}}=K u_{\tau} / U_{0}
$$

(2) The inner region of the boundary layer up to the apex is sufficiently thin for the cross-flow integral $\left(\delta_{2}\right)$ to be obtained by assuming that the outer region extends over the whole boundary layer.

The above conditions are in general satisfied by a pair of triangles but the data suggest that, for unseparated boundary layers at least, the definition can be made unique by adding the restriction that the included angle at the apex should be obtuse.

An example of the many profiles that fit this equivalent triangle closely is profile 1228 shown in Fig. 11. Such profiles are confined to the region of the flow upstream of the free-stream inflexion point. Profile 2598 in Fig. 11 is an example of those profiles which are quite well correlated by equation (9) although they are not well represented by a triangle on the polar plot.

Also shown in Fig. 11 are two profiles which are not so well correlated by equation (9). Profile 2998 is representative of these profiles on $Z=28$ and 30 inches for which, as shown in Fig. 10, measured values of $\beta_{0}$ are less than given by equation (7). These are decaying profiles in which the inner region appears to be decaying more rapidly than the rest of the profile. If this trend is continued a profile will be reached having $\beta_{0}=0$ but $\delta_{2} \neq 0$, which is a condition that cannot be represented by an equivalent triangle. It must be assumed therefore that, for a free-stream flow that undergoes one or more inflexions, as soon as $\beta_{0}$ passes through zero for the first time equation (9) and the equivalent triangle concept in its present form cannot be applied to the flow thereafter.

Profile 2198 shown in Fig. 11 is quite clearly not represented by its equivalent triangle and in common with other profiles through the separated region the value of $\beta_{0}$ is much greater than the value given by equation (9). These are the profiles which have been excluded from Figs. 9 and 10. Profile 2198 could be described as a 'cross-over' profile though it should be appreciated that the twist of the velocity vector $(\partial \beta / \partial y)$ in the outer region $(u / U>0.8)$ is qualitatively the same as would occur in the potential flow around the obstruction with the floor boundary layer represented by its displacement thickness. Profile

2198 also exhibits quite clearly the characteristics of a 'double' boundary layer in which the inner and outer layers are displaced by about $35^{\circ}$ and have quite different upstream histories.

It is concluded that equation ( 9 ) with a constant value of $K=19.45$ correlates the unseparated boundary layer data obtained in this experiment, although many of the profiles do not fit Johnston's triangular model well.

### 5.2. Logarithmic Plots.

Examples of the present data are shown in Fig. 12 plotted as $\mathbf{u} / U$ against $\log _{10}(y U / v)$. Also shown are the components of velocity, $u / U$ and $w / U$, and the function $u \sec \beta_{0} / U$. As in Fig. 6 the values of $y$ used in this figure are corrected for displacement effects by +0.004 inch . The function $u \sec \beta_{0} / U$ was used in Part 1 because it generally exhibited a linear logarithmic region which, it was suggested, gave the best estimate of the skin friction by the method proposed by Clauser ${ }^{9}$ for two-dimensional flows. These plots are compared in Fig. 12 with the 'Clauser' lines corresponding to the values of skin friction deduced from the Preston tube and razor blade measurements. As mentioned in Section 3 the inner region of most of the profiles is thick (up to $0.1 \delta$ ) and so covers much the same portion of the boundary layer as does the logarithmic law in two-dimensional boundary layers. In this region $\mathbf{u} / U$ and $u \sec \beta_{0} / U$ are very nearly equal, and as shown in Fig. 12, they both exhibit a linear logarithmic region which is in close agreement with the Preston tube and razor blade lines. The best examples shown are profiles 2416, 2808 and 2800 . For some profiles, for which the inner region is thinner (e.g. profile 1624), $u$ sec $\beta_{0} / U$ produces a longer logarithmic region than $\mathbf{u} / U$ whereas for other profiles (e.g. 2008 and to a very small extent 2400) the opposite effect is produced. Profiles in the last group are either within the separated region or very close to the separation line and should probably be corrected for vertical static pressure gradients which will tend to increase the velocity in the region of $\log _{10}(y U / v)$ equal to about 4.5 and so improve the agreement between the data and the 'Clauser' lines.

It is concluded that the use of the function ( $u \sec \beta_{0} / U$ ) to predict the skin friction in a three-dimensional boundary layer by the method proposed by Clauser for two-dimensional flows is satisfactory for all the data given in both parts of this Report with the possible exception of profiles within the separated region.

The proposal discussed in Part 1 that the $u \sec \beta_{0} / U$ profile might be treated as a two-dimensional equivalent of the actual three-dimensional boundary layer for the purpose of making use of existing two-dimensional skin-friction laws has not been tested with the present data owing to the lack of a twodimensional skin-friction law applicable to the present pressure gradients.

### 5.3. Mager's Cross-Flow Profiles.

In Part 1 it was shown that Mager's cross-flow profile ${ }^{10}$

$$
\begin{equation*}
w / u=(1-y / \delta)^{2} \tan \beta_{0} \tag{10}
\end{equation*}
$$

did not fit the data presented. Nine profiles from the present data are compared in Fig. 13 with equation (10) and it is readily seen that there is little agreement. The data are scattered widely about the line representing equation (10) which is inevitable in view of the wide variations of $\partial \beta / \partial y$ in the inner region and in the limit as $y \rightarrow 0$ in particular (see Section 5.1). By comparison equation (10) restricts the limiting twist to

$$
\underset{y \rightarrow 0}{L t}(\partial \beta / \partial y)=-\sin 2 \beta_{0} / \delta .
$$

Further support is therefore given to the conclusion of Part 1 that this type of representation is too simple and restrictive.
5.4. Coles's and Thompson's Profiles.

Fig. 14 shows a comparison between selected profiles from the present data and simple extensions of Coles's ${ }^{11}$ and Thompson's ${ }^{12}$ two-dimensional profiles to three dimensions. These extensions, which are
discussed in Part 1 result in profiles in the direction normal to the surface shear stress having the shape of Coles's wake function and one minus Thompson's weighting function, and are both represented by one curve on Fig. 14. The data do not fit the curve (Fig. 14) and produce much wider variations than were found in Part 1. The reason for these wide variations of the present data is the same as given in Section 5.3 for similar variations about Mager's cross-flow profile.

## 6. Conclusions.

Extensive information is given of a turbulent three-dimensional boundary layer produced by an obstruction placed in a two-dimensional boundary layer flow. The flow is dominated by the large pressure gradients produced by the obstruction and the influence of the shear stress is restricted to the region of the flow close to the surface. Also, in the region of the separation line, the measurements show that the normal boundary layer approximations are invalidated by significant pressure gradients through to layer.

The analysis presented in the Report suggests that the experimental data have been obtained with an acceptable accuracy and the data have been compared with several existing theories of two and threedimensional boundary layers.

The greater part of the data in this part of the Report relates to the flow downstream of a free-stream inflexion and the velocity profiles do not fit in closely with Johnston's triangular model. Data obtained ahead of the inflexion point do fit the triangular model quite closely, as did the data of Part 1. In spite of these limitations the triangular model has been used to derive an equation relating the skin-friction vector to other boundary layer parameters and this equation correlates all the unseparated boundary layer data. The equation will fail in separated regions and sufficiently far downstream of an inflexion point that the cross-flow angle at the surface has returned to zero.

The method described in Part 1 for deducing the skin friction in three-dimensional boundary layers using the logarithmic plot is found to be equally satisfactory for the data given in this part.

Mager's cross-flow profile and simple extensions to three dimensions of existing methods of representing two-dimensional profiles, using Coles's wake function and Thompson's weighting function, are all shown not to fit the data and in particular they are shown to be too restrictive to describe adequately the more complicated profile shapes that occur downstream of a free-stream inflexion.

## LIST OF SYMBOLS

| $C_{f_{0}}$ | Skin-friction coefficient based on tunnel reference kinetic pressure |
| :---: | :---: |
| $C_{p}$ | Static-pressure coefficient based on tunnel reference kinetic pressure |
| K | Constant (see equation (4)) |
| $n$ | Axis in the plane of the surface and normal to the skin-friction vector |
| $U$ | Free-stream velocity |
| u | Local velocity vector within boundary layer |
| $u$ | Component of $\mathbf{u}$ parallel to $\mathbf{U}$ |
| $u_{\tau}$ | Skin-friction velocity defined by $u_{\tau}=\sqrt{\tau / \rho}$ |
| $v$ | Component of velocity in $y$ direction |
| $w$ | Component of $\mathbf{u}$ normal to $\mathbb{U}$ |
| $X$ | Cartesian co-ordinate (see Fig. 2) |
| $y$ | Displacement of probe centre from surface |
| Z | Cartesian co-ordinate (see Fig. 2) |
| $\alpha$ | Angular displacement of free-stream (uncorrected) |
| $\alpha^{*}$ | Corrected value of $\alpha, \alpha^{*}=\alpha-0.1$ degree |
| $\beta$ | Boundary-layer cross-flow angle. The angle between $\mathbf{u}$ and $\mathbf{U}$ |
| $\beta_{0}$ | Value of $\beta$ in the limit as $y$ tends to zero |
| $\gamma$ | Defined by equations (5) and (6) |
| $\delta$ | Boundary-layer thickness $y=\delta$ at $\mathrm{u} / U=0.995$ |
| $\delta_{1}$ | $\int_{0}^{\delta}(1-u / U) d y$ |
| $\delta_{2}$ | $-\int_{0}^{\delta}(w / U) d y$ |
| $v$ | Kinematic viscosity of fluid |
| $\rho$ | Density of fluid |
| $\tau$ | Skin friction |

[^0]:    *Part 1 replaces R.A.E. Technical Report 69041 -A.R.C. 31362.
    Part 2 replaces R.A.E. Technical Report 69 137-A.R.C. 31721.

[^1]:    *A recent two-dimensional method ${ }^{3}$ uses the momentum equation without integration in combination with the time averaged form of the turbulent energy equation along a mean streamline. This method solves the equations directly by the use of a computer but relies on auxiliary equations relating the time averages of various turbulent quantities.

[^2]:    *No displacement effect has been applied to the $y$ co-ordinate. Preliminary tests with identical probes constructed of tubes of $0.028,0.020$ and 0.012 in outside diameter were unable to isolate the displacement. It is expected to be of order 0.004 in but may not be the same for total head as for yaw balance. This would complicate any correction considerably.
