# LOW-SPEED MIND-TUNGL MBASUREINNS OR THE LIFT, DRAG AND PITCHING WOMANT ON mPRe SYMMERRICAL OGEE-MLIGG MODELS AND ON A SYMIETRICAL SLENDER VIIG-BODY MODEL 

by
D. A. Kiruy, B.Sc., A.C.G.I., D.I.C.

## SUMAERY

Measuremonts have been made of the lift, drag and pitching moment of three ogee models and a wing-body model, all having a slendemess ratio (semispan/root chord) of 0.209 . The associated surface flow patterns were al:so obsurved.

Although the models were symmetrical and did not represent strictly comparable fully optimised designs of possible layouts for a supersonic transport, sone useful low-specd acrodynamic comperisons between the integrated or ogce models and the wing-body model were obtained. The results show:-
(i) very similar lift characteristios,
(ii) a slightly smeller arag for tho wing body model,
(iii) better static longituainal stability characteristics for the wingbody model, especially whon the wing planform was not faired smoothly into the body.

Attempts to improve the longitudinal stability of one of the ogee wings, by minor planform modifications at the rear of the wing intended to reduce the foward movement of acrodynamic centre with incidence, were largely unsuccessful, but provided some useful deta on the effect of trailing-edge shape. For the wing-body model, drooping the nose was a successful modification and it is suggested that a drooped nose version of the wing-body model (without any planfom filict) would havo gooc statio longiludinal stability.

## TNTRODUGTION

This Note gives the results of $4 \mathrm{ft} \times 3 \mathrm{ft}$ low-speed tunnel tests made as part of a general experimental investigation of the characteristics of various layouts for supersonic transport aircraft intended to cruise at Mach numbers in the region of 2.0. These layouts have included some configurations where the body is completely integrated with the wing and the resulting planform is ogee in shape, and others where the combination or a wing and body is more easily identifiable. The investigations reported here were concerned with the flow properties and the static longitudinal characteristics of four symmetrical models, namoly three wings with ogec planforms and integrated bodies and one wine body comination.

For all four models the slenderness ratio $\mathrm{s} / \mathrm{c}_{\mathrm{o}}$ was 0.209 while the planform area ratio $p(=S /$ bo $)$ was $0.430,0.450$ and 0.467 for the ogee wings, and 0.455 for the wing-body combination. Allied stuaies of the effects of lengthwise and spanwise camber on the longitudinal characteristics of the $p=0.450$ ogee planform are reported elsewhere.

In addition to the measurements on the four basic models, some attempts to alleviate the forward movement of aerodynamic contre with increase of lift were made on the $p=0.430$ ogee wiing and on the wing-body combination. The nature of these modifications is described in sectior 2 and the results discusped in section 3.3. A simplified wing-body model was also tested to find the contributions of the body and the planform fillets to the stability of the complete model, and an analysis of these tests is presented in section 3.4.

Studies of the flow over and around these models were made using surface flow and smoke techniques to see if the changes in sweep-back along the leadingGdge and/or the presence of a body destroyed the unified flow originally aimed at in these slendur shapes. The results of these observations are discussed in section 3.1.

## 2 DETATLS OF MODELS ATD TESTS

The roin dimensions of all the models are given in Tlable 1. The $p=0.430$ ogec planform was taken from a project study by Hawker Siddeley Aviation, whilst the other tro (with $p=0.450$ and 0.467) were designed by Dr. J. Weber of RoA.E. to give more gradual changes of smoep-back along the leading-edge (Fig.1). The cross sections of all three models werc simplified versions of the firms proposed "intecrated" layout (laible 1 and $\mathrm{Fig} \cdot 1$ ).

The wint-body model ( $p=0.455$ ) was made to a planform and sections obtained from an early Bristol Aircraft design by whearing the cambered sections of that desien to oive a symmetrical model. The planform of the wing blended via a fillet into a narrow strake on cach side of tho body (Figs. 2 and 3). A furthor model ( $r=0.450$ ) was made with a detachable body and without fillets or strekes in order to investigato their effocta* . The planform of this model

* Since one model had fillets and strakes and the other had neithor, the terms "with fillet" and "without fillet" will be used in referring to these models in the test and figures.
is compared with that of the $p=0.450$ ogee in Fig. 3 . All the models were made of wood.

Measurements of the lift, drag and pitching moment of the models were made in the $4 \mathrm{ft} \times 3 \mathrm{ft}$ low-speed tunnel during 1960 , using the normal wire rig and overhead balance. Most of the tests were made at a tunnel speed of $200 \mathrm{ft} / \mathrm{sec}$, but, because of model vibration, for the ogee models at incidence above $20^{\circ}$ the speed was reduced to $100 \mathrm{ft} / \mathrm{sec}$. The incidence range was from $-4^{0}$ to $26^{\circ}$. The Rernolds based on the overall model lengths and a speed of $200 \mathrm{ft} / \mathrm{sec}$ ranged between 2.6 and $2.9 \times 10^{6}$. Except for a few surface flow tests, the transition was left free.

Since the tests showed a forvard movement of acrodynamic centre with increase of lift, methods of alleviating this mild "pitch-up" were sought. For the ogec models, the effoct of providing extra non-linear lift at the rear was investigated by attaching brass plates to the lower surface of the $p=0.430$ model to exterd the planform; six shapes were tried (Table 2 and jig. (a)). On the wing-body model, a decrease in the lift on the forebody was attempted, both by simple lincar droop at tho nose and by a parabolic droop (Table 2 and Fig. 4 (b)).

Visualization of the flow over the upper surface of all the models was obtained using lampblack suspended in paraffin ${ }^{2}$ at tunnel speeds of up to $180 \mathrm{ft} / \mathrm{sec}$. Some extra observations of the flow above the wing-body models were made at $10 \mathrm{ft} / \mathrm{sec}$ using liquid titanium tetrachloride which fumes in moist air. The models were transferred from the wire rig to a rear sting mounting for both these flow tests.

The results of all the balance measurements are presented in Tables 3-7 and discussed in section 3. The tunnel constraint corrections applied to the balance measurements include the effect of model length calculated by the method of Ref.3. Since breakdow of the leading-edge vortices did not occur for the range of incidence tested, there was only a small wake blockage correction.

## 3 RESUTTS ARD DISCUSSION

### 3.1 Flow visualization

From very low incidences the surface flow patterns on the ogee wings showed the presence of the leading-edge vortices which dominate the flow over slonder wings with sharp edges. These vortices were continuous for all the models over the whole range of incidence coverca; differences between the wings being limited to variations in the positions of the primary vortex. The spanwise looation of this vortex oan be conveniently specified by using the point of inflexion in the flow lines which aro produced in the upper surface flow pattorns. Tig. 19 shows such patterns for the three ogee wings at an incidenoe of $15^{\circ}$. At this incidence, at $50 \%$ root chord the spanvise positions of the primary vortex were as follows:-

$$
\begin{array}{llll}
\mathrm{p} \\
\mathrm{y} / \mathrm{s}, & 0.430 & 0.42 & 0.450 \\
0.53 & 0.467 \\
\hline
\end{array}
$$

whilst for all three wings the secondary separation ocurred at $\mathrm{y} / \mathrm{s}^{\prime} \bumpeq 0.7$.

At lower incidences, up to about $5^{\circ}$, there were some signs of further flow scparations inboard of the primary vortex attachment lines on the forward part of the wings. However, these wore considered to be an effect of the low Reynolds number of the tests and were eliminated when a transition wire was fixed round the nose.

For the complete wing-body modcl the flow was more complex. At $5^{\circ}$ of incidence the flow was still attached on the body with the wing leading-edge separcition starting in the wing fillet region at about $30 \%$ of the body length. Separation of the flow from the upper surface of the body started just below $10^{\circ}$ of incidence and by $a=15^{\circ}$ was clearly marked (Fig.20), resulting in the formation of body vortices which trailed back down the centre of the model. The scparation from the wing leading-edge started a little nearer the nose at the highor incidences but, because the strakes on the side of the body were small and not very sharp, the scparation over the range of incidence tested never began ahead of about $25 \%$ of the body length. As incidence was increased and the wing vortices grow in strength and moved inboard, they pulled the body vortices down towards the model, so that, Collowing the onset of body asymmetry at $a \bumpeq 20^{\circ}$, the body vortices wrapped in succession around the port wing vortex (Fie.20). This was clearly demonstrated by the smoke tests.

Similar results were obtained on the model without a fillet. In this configuration, the length of the body ovcrhang was greater and at full-scale the onsct of body-vortex asymmetry at zero sideslip might be expected to occur at a lower incidence than that for the layout with fillet. Some of the effects of vortcx asymnetry, and the limitations of the small-scale $4 \mathrm{ft} \times 3 \mathrm{ft}$ tunnel models in assessing the incidence at which asymmetry commences, are discussed in Rer.4.

A noticeable feature of these flow tests made on a sting rig was the steadinoss of the winc-body models compared with the ogee models. These latter were so unsteady at the higher incidences that the tunnel speed had to be roduced to $60 \mathrm{ft} / \mathrm{scc}$. Similar problcms worc experienced with the ogee models in the force tests; and furthermore, some comparative measurements of damping in yaw on a $p=0.150$ ogee modol and a wing-body model have, shown that the ogee alone experienced nogative daming in yaw at high incidence ${ }^{4}$.

### 3.2 Liftt drag and pitching momenty of the basic shapes

The lirt, drag and pitching moment coefficients of the four models are given in Tables 3 and 5. Theso cocficicients have been calculated using the arcas and acrodynamic meen chords of the whole planform in each case. Lif't curves are plotted in Fig. 5 for the three ogee wings and in Fig. 9 for the complete wing-body model. The lift coofficients for all these models, all having the same slenderness ratio are very similar, though Fig. 5 shows a slight tondency for lift at a given incidence to decrease with increasing value of $p$. At $15^{\circ}$ of incidonco, the four molels havo lift coofficients some $6 \%$ higher than thoso from the mean curve drawn in Ref. 5 for gothics ( $p=0.667$ ) and deltas $(p=0.5)$. These lattor were flat plate models and Ref. 5 shows that taking into account thickncss would widen the difforences in lift between the prosent shapes and the pure $\varepsilon$ othics and doltas. Further systematic work on the effect of planform and thickness on lift is clcarly desirable. This is partially being covired by tests at prosont in progress on a series of wings spocially designed to investigate more systematically the effect of planform on aerodynamic centre position.

The lift-dependent drag factor and the lift/drag ratio plotted in Eig. 6 for the ogee models (transition free) show little effect on the approach drag within the range of $p$ tested, the differcnce in lift-dependent drag factor arising mainly from the change in aspect ratio, i.e. $\mathrm{K} / \mathrm{A}$ is nearly constant. Fig. 10 shows some advantage for the wing-body model.

The pitching moments plotted in Fig. 7 for the ogees, and in Fig. 11 for the wing-body configuration with and without fillets, show the vital importance of caref'ul choice of planform as regards the static longitudinal stability.

### 3.3 Aerodynamic centre position and attempts to improve the static ionkitudinal stability

For most of the expected subsonic range of lift coefficient 0.1 to $0.7^{*}$, the positions of the acrodynamic contro moves forward with increasing lift coefficient (Fig.13). This forward movement is most marked for the ogee wings, particularly in the $C_{L}$ range 0.1 to 0.5 . In Fig. 14 the pitching moment coefficients for the throc ogee models and the wing-body model with and without fillets havo been replotted about moment centres chosen to give ncutral static longitudinal stability at $C_{L}=0.5$. It is evident that for the three ogee wings tested the amount of elcvator needed to trim at low specd and the amount of camber needed to trim at high speed will be greater than that needed for the wing-body layout, assuming similar rearward movements of aerodynamic centre with Mach number, and no centre of gravity change through the specd range.

Attempts to reduce the rate of forward movement of the aerodynanic centre with lift coefficient wore made for both ogec and wing-body layouts. Thus, for the ofce model $p=0.430$, six different shapes of extension to the rear of the plenform wore made, to see if more non-linear lift could bo obtained aft of the moment centro by adding to the area beneath the leading-edge vortices (Fig. 4 (a)). An analysis of the results given in Table 4 and plotted in Fig. 8 shows the following changes in static stability margin ( $\Delta \mathrm{hn}$ ) vetween $\mathrm{C}_{\mathrm{L}}=0.1$ and 0.7 as comparea with the basic wing. Dhn is given as a fraction of the contre-line chord $c_{0}$ which is the same for all seven configurations.

| Basic <br> wing | A | B | C | D | F | F |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| 0.039 | 0.050 | 0.044 | 0.049 | 0.051 | 0.038 | 0.022 |

Only the large rectangular extension $F$ yields any reduction in the rate of forward movement of the aorodynamic centre.

On the wing-body model the effect of reducing the non-linear lirt at the front was tried, the forebody being drooped to reduce the local angle of incidence. Such nosc droon is desirable for pilot's view in the approach and * Assuming an approach lift coefficient in the neighbourhood of 0.5 airworthiness requirements will demand that the aircraft be adequately cleared to $C_{L} \approx 0.7$.
to delay the onset of body vortca asymmetry ${ }^{4}$. Results with simple droop angles of $10^{\circ}$ and $20^{\circ}$, as well as with a parabolic droop, are plotted in Figs. 9 and 12. For these models the changes in the static-stability margin $\Delta \mathrm{hn} / \mathrm{c}_{\mathrm{o}}$ between $C_{L}=0.1$ and 0.7 are listed below.

| Basio <br> model | Model cut for <br> droop tests | $10^{\circ}$ droop | $20^{\circ}$ droop | Parabolio <br> aro droop |
| :---: | :---: | :---: | :---: | :---: |
| 0.015 | 0.014 | 0.009 | 0.008 | 0.006 |

The gains due to droop are not large, but are sufficient to ensure that the wing-body layout even with a fillct does have a nearly linear pitching moment $v$ lift relationship.

For both integratod and wing-body layouts the forward movement of the aerodynamic centre with increase of lift will be greater when camber is applied to the wing, but there is somo evidence that for cambers producing the same pitching moment increment this change is smaller for the wing-body than the integrated layout ${ }^{6}$.

The positions of the aerodynamic centre at a lift coefficient of 0.5 for all the models tosted are shown in FiE.15, plotted against the position of the controid of area of their total planforms. The figure also shows the mean line taken from Ref. 7 for thick wings. Analysis of the results with trailing-edge extcnsions to the $p=0.430$ ogec model shows that if the length from the apex of the wing to tho centre on the treiling-edge of the extension is used as the referonce longth in defining the positions of the aerodynamic centre and centroid of area thon the corodynamic centre position of all the variants A-F correlate woll with the basic wing position along a line parallel to the line taken from Rer. 7.
3.4 Contribution oi the body and fillct to the lift and pitching moment of the winctony model

In Wigs.16 and 17 the lift and pitching moment cocfficients of the two wing-body models bascd on the area of tho wing alonc aro plotted together with the results for the wint alone. The effect of the body and fillet on the overall lirt of the wing is vory small and the lif't curve using the new roference area, i.e. that of a mild cethic wing is idention with that taken from Ref.5. A chordwise redistribution of lift is indicated by Figs. 16 and 17. This is shown most clacily by the position of the centre of pressure (Fig.18), and although the addition of the body to the wing gave a more constant centre of pressure position through the range of incidence, the subsequent addition of the fillet oaused a rapid forward movement of the centre of pressure at the higher incidences. The effect of this lattor addition on the aerodynamic centre position is shown in Fig.13.

Since the size of the strakes on the complete model was insufficient to fix the bogiming of the leading-cdge separation at one point for all incidences, while, with the mid-wing position the wing vortices failed to
oolleot the body vortices at the lower incidences and to prevent them trailing over the fin position, it is considered that fillets of this type serve no useful purpose.

## 4 CONCLTISIONS

The tests show the effect of a limited range of planform shape variation on the low-speed static longitudinal stability of slender supersonic transports and enable some low-speed aerodynemic comparisons to be made between the integrated and wing-body layouts.

For the three ogee planforms tested, the changes in leading-edge sweep were gradual enough not to impair continuous vortex development along the leading edge. With the wing-body arrangemont, flow separations from the body at modorate incidence gave rise to body vortices which trailed back down the centre of the modcl. At high incidences these body vortices became asymmetric and wrapped round the wing leading-edge vortices. The prosence of a plenform fillet in the wing-body junction, continued forward as small strakes on the side of the body, yiclded no improvements and introduced uncortainty in the position of the start or the wing leading-cage vortices. Iurthor work on other wingbody arrangements not reported hore has domonstrated the variations in wing and body vortex interaction which oan be obtaincd as the relative strengths and positions are changed.

All the models tested had the same slendurness ratio and showed virtually no change in lift coefficient, bascd on the totel planform area, within the small range of $p$ testod. Thesc lift coefficionts were some $6 \%$ higher than those neasurud earlicr for gothic and delta mings of the same slenderness ratio but, assessing the lift cocfficient of the wing-body models on the area of the basic wing gave the same lilt as measurod on the ring alone and on the gothic and delta wings.

Analysis of the pitchine momonts showd a forward movement of aerodynamic contre with increase of lift on all the models, this boing more pronounced for the ogee planforms. Adding wing root planform fillets to the wing-body model increased the forvard movement of acrodynamic contrc. Attempts to reducc this movement on onc of the ogee models by trailing-edge extensions were not very successfful. Howcver, on the complete wing-body model drooping the forebody yielded some bencfit, and this improvemont taken in conjunction with the effect of the fillet indicates that a drooped nose version of the wing-body model without a fillet chould be virtually fres from forward movement of the aerodynamic contre with incidence.

| 100 | 21.67 | 0.15 | - | 10.29 | 10.29 | 10.29 |

All the transverse sections were formed by drawing tangents from the wing edges to the arcs given by the contre radius. The planform of the $p=0.430$ wing was taken from a project study by iluwher fidiacloy dviation Ltd and the obhers defined by the relationships

$$
\begin{gathered}
s(x)=1.2 x-2.4 x^{2}+2.2 x^{3}+3 x^{4}-3 x^{5} \\
\text { for } p=0.450
\end{gathered}
$$

and

$$
\begin{gathered}
s(x)=1.4 x-5.3 x^{2}+12.4 x^{3}-9.5 x^{4}+2 x^{5} \\
\text { for } p=0.467
\end{gathered}
$$

The leading edge radius was of the oraer of 0.01 in .

## A.R.C. CP NO. 846

LOW-SPEED WIND-TUNNEL MEASUREMENTS OF THE LIFT, DHAG AND PITCHING MOMENT ON THREE SYMMETRICAL OGEE-WING MODELS AND ON A SYMMETRICAL SLENDER WING-BODY MODEL. Kirby, D.A. November 1963.
533.6.013.13 : 533.6 .013 .12 : 533.6.013.152 : 533.695.12 : 533.693 .4

Measurements, have been made of the lift, drag and pitching moment of three ogee models ard a wing-body model, all having a slenderness ratio (semispan/root chord) of 0.209 . The associated surface flow patterns were also observed.

Although the models were symmetrical and did not represent strictly comparable fully optimised designs of possible layouts for a supersonic transport, some useful low-speed aerodynamic comparisons between the integrated or ogee models and the wing-body were obtained. The results show:-

L.CV.-SPEED WIND-TUNNEL MEASUREMENTS OF THE LIFT, DRAO AND PITCHING MOMENT ON THREE SVINETRICAL OGEE-WING MODELS AND ON A SYMIETRICAL SLIENDER WING-BODY MODEL. Kirby, D.A. November 1963.

Measurements have been made of the lift, drag and pitching moment of three ogee models and a wing-body model, all having a slenderness ratio (semispan/root churd) of 0.209 . The associated surface flow patterns were also observed.

Although the models were symmetrical and did not represent strictly comparable fully optimised designs of possible layouts for a supersonic transport, some useful low-speed aerodynamic comparisons between the irtegrated or ogee models and the wing-body were obtained. The results show:-
(i) Very similar lift characteristics,
(ii) a slightly smaller drag for the wing-body model,
(iii) better static longitudinal stability characteristics for the wing-body model, especially when the wing planform was not faired smoothly into the body.

At,tempts to improve the longitudinal stablility of one or the ogee wirgs, by minor planform modifications at the rear of the wing intended to reduce the forward novement of aerodymamic centre with incidence, were largely unsuccessful, but provided some useful data on the effect of trailing-edge shape. For the wing-body model, drooping the nose was a successiul modification and it is suggested that a drooptc rose version of the wing-body model (without any planform fillet) would have good static longitudinal stability。
(i) very similar lift characteristics,
(ii) a slightly smaller drag for the wing-body model,
(1i1) better static longitudinal stability characterist ics for the wing-body model, especially when the wing planform was not faired smoothly into the body.

Attempts to improve the longizudinal stability of one of the oget wings, by minor planform modifications at the rear of the wing intended to reduce the forward movement of aerodynamic centre with incidence, were largely unsuccessful, but, provided some useful data on the effect of trailing-edge shape. For the wing-body model, drooping the nose was a successrul modification and it is suggested that a drooped nose version of the wing-body model (without any planform fillet) would have good static longitudinal stability.
(i) very similar lift characteristics,
(ii) a slightly smaller drag for the wing-budy model,
(ili) better static longitudinal stability charecteristics for the wing-body model, especially when the wing planform mas not faired smoothly into the body.

Attempts to improve the longitudinal stabllity of one of the ogee wings, by minor planform modirications at the rear of the wing intended to reduce the forward movement of aerodynamic centre with incidence, were largely unsuccessful, but provided some useful data on the effect of trailing-edge shape. For the wirg-body model, drooping the nose was a successful modification and it is suggested that a drocied nose version of the wing-body model (without any planform fillet) would have good static longitudinal stability.
